A STUDY OF THE LESIONS IN THE VASCULAR SYSTEM IN FATAL CASES OF CHRONIC NEPHRITIC TOXÆMIA OF PREGNANCY

MALIGNANT NEPHROSCLEROSIS¹

JOHN L. McKELVEY M.D. BALTIMORE MARYLAND
Department of Obstetrics, Johns Hopkins Hospital and Medical School
H. E. MACMAHON M.D. M.R.C.P. BOSTON MASSACHUSETTS
Department of Pathology, Tufts College Medical School

THE toxemias of pregnancy present a series of problems which are of the utmost importance. These have been attacked from a variety of viewpoints including the study of the histopathological lesions, the chemical and metabolic changes, and the clinical aspects. None of these studies can be completely satisfactory without information as to etiology, and this is entirely lacking. However, material is accumulating which is adding much to the understanding of the processes. It is the purpose of this paper to present observations on the lesions in the vascular systems of those patients who have been injured by pregnancy toxemias and who have eventually died after a typical clinical course. These lesions have not been adequately described in relation to pregnancy toxemias but have received much attention in other conditions under the term malignant nephrosclerosis by Volhard and Fahr (1914), Fahr (1934) Schuermann and MacMahon (1933), and others. A study of the literature shows that the frequency with which this condition occurs in relation to pregnancy toxemias has been overlooked. Descriptions of the so called obstetrical chronic nephritis also lack a realization of the similarity of the two conditions.

The material is that obtained at autopsy on patients who have died on the obstetrical service of Johns Hopkins Hospital. It does not represent in any way the total incidence of the condition since the vast majority of the women who die of chronic nephritis following a pregnancy toxæmia do not return to the obstetrical service at this time. For completeness, consideration was given to the histories of all patients who were indexed as having died of nephritis. The material from all upon whom autopsies had been done was obtained and, wherever possible the kidney, adrenal and pancreas were studied. To the usual staining procedures were added the connective tissue stain of Mallory and the elastic tissue stain of Verhoeff.

This study does not include the deaths from eclampsia. As will be seen, it does include in so far as autopsy material allowed, all other deaths in which kidney lesions were clinically suspected. Two groups of material emerged. There was, first, that group in which a pregnancy toxæmia had occurred, hypertension had persisted postpartum and after a varying period of time, uræmic death had ensued. This group constitutes the subject of the present study.

Brief consideration has also been given to

the second group studied. In these patients, we have no history of prolonged severe hypertension and the condition may be considered as acute and of short duration. These have been included for comparison and for the purpose of stressing the fact that there is an essential histological difference between the lesions of the acute toxemias of pregnancy and those which may ultimately lead to the death of the individual concerned. A difference in etiology or mechanism of production is not implied.

In 1927 a toxemia clinic was established at Johns Hopkins Hospital with the object, not only of giving special attention to those patients who show toxemias during pregnancy but also of following these patients after delivery for treatment and for the collection of data. This clinic has yielded valuable information particularly as to the ultimate prognosis for those patients upon whom a diagnosis of chronic nephritis following a pregnancy toxemia has been made. This will be considered below. It has also served to focus attention upon the end stages of the disease and is steadily producing more and more material for study of the condition.

It should be stated that the term chronic nephritis is used here in the sense employed by Stander and Peckham (1926) in their classification of the toxemias of pregnancy. This diagnosis is made during pregnancy when the blood pressure rises above 155 millimeters mercury systolic and/or 100 millimeters mercury diastolic, with or without albuminuria and in the absence of signs and symptoms of pre-eclampsia. The previous history and the blood chemistry findings, the type and degree of the urinary findings, and the physical examination with special attention to the eye grounds will temper the diagnosis. Peckham and Stout (1931) showed that one fifth of the patients so diagnosed showed no demonstrable damage at subsequent examinations. On the other hand one-fourth of those diagnosed as of the low reserve kidney or pre-eclamptic type during pregnancy and the early puerperium were shown to have residual damage later. The immediate clinical diagnosis then is a loose one and must be controlled by prolonged observation after delivery. This gives

the second set of criteria for the diagnosis of chronic nephritis. The presence of a persistent hypertension of 150 millimeters mercury systolic and/or 100 millimeters mercury diastolic and/or a persistent albuminuria postpartum (Peckham and Stout 1931) allows such a diagnosis, while the absence of any of these makes it unlikely that the original toxemia has been of the chronic nephritic type.

Such a follow up will yield surprising information. Peckham (1931) has shown that of 74 eclampsias so observed 23 per cent showed ultimate evidence of chronic nephritis. Of the toxemic patients, excluding those with pernicious vomiting and eclampsia, 40 per cent showed residual damage. Some of these latter however were known chronic nephritics before the present pregnancy so that the incidence here expressed is not a proper expression of the incidence relation. But these figures do serve to point out the frequency with which permanent damage to the woman follows the toxemias of pregnancy. It should be pointed out that this is at variance with the observations of Heynemann (1924), Fahr (1924), Zondek and co-authors (1924) and Nevermann (1927) as reported by Bell (1932).

The next step is to consider what eventually happens to these women with chronic nephritis. Stander and Peckham (1931) reported on 135 women who had a chronic nephritic toxemia of pregnancy and who had been observed on the obstetrical service of the Johns Hopkins Hospital during pregnancy one or more times over a period of from 1 to 11 years previously. They found that 46 were dead and of these 37 had died of clinical nephritis. Of those alive 26 showed no evidence of permanent cardiovascular renal damage (the one-fifth error referred to above) while 30 had evidence of a severe chronic nephritis, and 20 showed signs of moderate chronic nephritis. Of the remainder no information was obtained.

It is shown then that this sequence of events toxemia of pregnancy chronic nephritis, and ultimate early death occurs with striking frequency. A causal relation might be presumed but is not established. It would seem that a careful histological study of the steps in the process might yield valuable information.

Fig 1 Interlobar artery showing vascular hypertrophy. Note particularly the thick muscular media. (Verhoeff's elastic tissue—Van Gieson connective tissue stains) $\times 88$.

Fig 2 Arcuate artery showing vascular hypertrophy. The media is thickened and well preserved. There is a connective tissue thickening of the intima and a well developed lamellar elastosis. (Verhoeff's elastic tissue—Van Gieson connective tissue stains.) $\times 88$

Until recently this was confined to a consideration of the lesions of eclampsia. The work of Zangemeister in directing attention to the tissue oedema and its extrarenal cause as a fundamental condition and of Hinselmann (1921-1924) in the study of capillary spasm, are too well known to require comment. The work of Volhard and Fahr on the kidney gave a new impetus to the study of that organ in the toxæmias. Their division of kidney disease into nephritis, nephrosis, and sclerosis clarified the obstetrical problems. Volhard (1918) pointed out that the kidney lesions seen in the toxæmias of pregnancy and particularly in eclampsia are not primarily degenerative but show a typical ischæmia of the glomeruli with marked secondary parenchymal changes. This directed attention once more to the vascular system. Heynemann (1920-1921) took issue with this, described the lesions of the toxæmias as a whole as degeneration in the glomerulus and the convoluted tubules and coined the term "pregnancy glomerulonephrosis" to describe it. He was careful to point out, however, that when blood appears in the urine or the systolic blood pressure goes above 165 or 175 millimeters mercury or when the blood pressure remains elevated following preg-

Fig 3 Lobular artery showing vascular hypertrophy with a connective tissue thickening of the intima, the internal elastic lamina is stretched and the outer muscular media still partially intact is narrow. Superimposed on this older process is a recent change with saturation of the intima with blood, partial thrombosis, focal disappearance of internal elastic lamina, and hemorrhage into the media and adventitia. (Hæmatoxylin and eosin.) $\times 140$

Fig 4 Lobular artery with branching afferent arteriole. There is intimal hypertrophy, connective tissue thickening of the intima, a deposition of fluid like ground substance beneath the endothelium, swelling of the endothelial cells, and collapse of the lumen. The muscular media in places is still easily recognizable. The smaller branches show occlusion of their lumina, thrombi, and a saturation of their walls with plasma and fibrin (Hematoxylin and eosin) $\times 95$.

Fig 5 Small lobular arteries. The adventitia is thickened, the media is largely replaced by connective tissue. One of the vessels shows a fusiform swelling of the basement membrane. There is a mucoid thickening of the intima, with few cells and an abundance of mucinous intercellular ground substance. The lumina are greatly narrowed. The endothelial cells are swollen. In such vessels one may trace the incorporation of endothelial cells into the underlying ground substance (Hematoxylin and eosin) $\times 295$.

Fig 6 Lobular artery showing hypertrophy. The muscle fibers of the media are large, stretched, and not easily recognizable. Internal elastic lamina stretched but intact. Lumen apparently obliterated due to great thickening of intima. In this thickened intima are concentric lamellae of cells, mucoid intercellular substance, newly formed elastic fibrils, scattered endothelial cells (Hematoxylin, eosin) $\times 35$.

nancy, the condition is likely to be a glomerulonephritis with proliferative lesions in the glomerulus as described by Volhard (1918). No attention was given by either of these authors to the vessels of the kidney other than the afferent arteriole and the capillaries of the glomerular tuft.

Many other investigators have examined and reported upon the kidney lesions of the various toxemias. Among these Bell (1932) describes a series in which pregnancy had occurred in the presence of pre-existing kidney disease. The microscopic findings are incomplete and his conclusion is that the kidneys show typical advanced chronic glomerulonephritis. Baird and Dunn (1933) also describe 5 cases of chronic nephritic toxemia with similar conclusions. Neither has given attention to the arteriolar lesions. Russel (1929) described similar lesions in a group which she designates "toxemias of pregnancy other than eclampsia." A search of the literature has revealed no complete description of the vascular lesions of those women who have

Fig. 7. Lobular artery showing hypertrophy. The muscle fibers of the media are large, stretched, and indistinct. The internal elastic lamina is thick and granular. The intima is greatly thickened by concentric lamellae of spindle shaped cells and intercellular fibrils embedded in a mucoid ground substance which near the lumen contains plasma and fibrin. Endothelial cells swollen and indistinguishable from underlying cells in ground substance. Leucocytes within lumen. (Hematoxylin and eosin.) $\times 585$.

Fig. 8. Lobular artery with small afferent arteriole. The lobular artery is almost completely transformed into concentric lamellae of cells and intercellular fibrils embedded in a mucoid ground substance. The lumen is apparently obliterated. The endothelial cells are swollen and may be traced into the underlying ground substance. The wall of the small afferent arteriole is saturated with plasma and fibrin. (Hematoxylin and eosin.) $\times 350$.

Fig. 9. Lobular artery. The muscular media is replaced by connective tissue. The intima is greatly thickened by concentric lamellae of spindle shaped cells and intercellular fibrils, embedded in a vacuolated mucoid ground substance. The lumen is obliterated by a small fibrin thrombus. (Hematoxylin and eosin.) $\times 350$.

Fig. 10. Small lobular artery. Muscle fibers of media still recognizable—they are hypertrophied. The thickened intima is largely composed of a mucoid ground substance in which few cells and delicate fibrils may be seen. Endothelial cells are swollen and stain intensely. Lumen collapsed and nearly obliterated. (Hematoxylin and eosin.) $\times 425$.

Fig. 11

Fig. 11. A small lobular arteriole, almost completely replaced by a tube of coagulated plasma and fibrin. The lumen is very narrow, the endothelial cells are swollen. There is beginning granulation by proliferation of adventitial cells. (Hematoxylin and eosin) X 170.

Fig. 12. Small lobular artery showing a severe and fresh lesion. The lamina propria wall is split apart and saturated with plasma, red blood cells, and polymorphonuclear leucocytes. There are red blood cells and polymorphonuclear leucocytes within the lumen. (Hematoxylin and eosin) X 170.

Fig. 13. Afferent arteriole and glomerulus. The lumen of the afferent arteriole is distended with blood, the sub-endothelial basement membrane is fragmented and the wall is saturated with blood. There is an occasional dilatation of the afferent vessel just after entering the glomerulus. There is a hemorrhage into the vessel wall and into the framework of the glomerular tuft. Some of the capillaries of the glomerulus are collapsed, others show extreme dilatation with fragmentation of the basement membrane and hemorrhage into the capsular space and proximal convoluted tubule. The overlying epithelial cells are swollen, granular and some contain hemosiderin. (Hematoxylin and eosin) X 15.

Fig. 14. Afferent arteriole and glomerulus. Both are unusually large. The wall of the arteriole is saturated with plasma. The lumen is partially occluded with a fibrin

Fig. 12.

thrombus. The same changes are seen in portions of the glomerular tuft in which blood cells, plasma, and fibrin appear beneath the endothelium of the capillaries, often obstructing the lumen. The overlying epithelial cells, and cells of the capsule show degeneration and desquamation. There are scattered polymorphonuclear leucocytes and red blood cells, together with fibrin and precipitated protein within the capsular space. (Hematoxylin and eosin) X 151.

Fig. 5. Two glomeruli with their respective afferent arterioles. The walls of the afferent arterioles are saturated with plasma, fibrin, and fragmented red blood cells. Their lumina are partially thrombosed. In the one glomerulus the capillary tuft is collapsed, in the other the capillaries are overdistended with blood, the basement membrane is stretched, and there are red blood cells within the capsular space and convoluted tubules. (Hematoxylin and eosin) X 15.

Fig. 6. Glomerulus showing aneurysmal dilatation of the afferent vessel after entering the glomerulus. The lumen of this vessel is distended with red blood cells and the wall is saturated with blood and fibrin. Many of the capillaries contain red blood cells, others are collapsed. The walls of the capillaries are thickened by a reduplication of the basement membrane and also by an increase in the ground substance beneath the endothelium. (Hematoxylin and eosin) X 170.

died a clinically nephritic death following a chronic nephritic toxemia of pregnancy.

On the other hand, Volhard and Fahr (1914) and Fahr (1934) called attention to a condition which was characterized by marked elevation of blood pressure and a quickly fatal course with uræmic death. This appeared in individuals of middle life and about equally in males and females. The histological findings in the small arteries and arterioles throughout

the body were characterized by necrotizing changes of the wall, saturation of the walls with plasma and red blood cells and proliferation of the endothelium and connective tissue of the intima described as an endarteritis which often led to apparent occlusion of the lumen. These were found scattered throughout the body but particularly in the kidney and also in the pancreas, adrenal, gastrointestinal tract and brain. The changes in

Fig. 13.

Fig. 14.

Fig. 15

(Legend on opposite page)

Fig. 16

the kidney involved not only the large and smaller vessels, but also the glomeruli and tubules. Unlike the lesions of diffuse glomerulonephritis which are found in all glomeruli, the changes here tend to be focal, involving single or groups of glomeruli in a degenerative and inflammatory process. The tubules present a picture in which the changes in the lining epithelium vary from slight degeneration

to necrosis and desquamation. This they described as a pathological entity under the term malignant nephrosclerosis. This work was confirmed and extended by Schnermann and MacMahon (1933) and others. Much work has been carried on in studying this condition, but the etiological relation of the toxæmia of pregnancy has not as yet been described.

Fig. 17, left, boy. Glomerulus, showing an organizing process with proliferation of endothelial cells which form a tumor-like projection growing into the dilated afferent arteriole, partially occluding the lumen. There are still residual fibrin and fragmented red blood cells within the structure of the glomerulus. The proliferating endothelial cells are separated by a newly formed delicate intercellular fibrillar reticulum. The basement membrane of the capsule is absent along one side and is often and fibrillated along the other. (Haematoxylin and eosin) $\times 65$.

Fig. 18, right, above. Glomerulus, showing a still later stage than Figure 7. At the pole of the glomerulus, proliferating endothelial cells together with their intercellular fibrillar reticulum have formed small granuloma-like nodules. This represents a late stage in the organization and repair of the injured afferent vessel as seen in Figure 16. The lumen of the afferent arteriole is not completely occluded,

and the capillaries of the glomerular tuft contain a moderate amount of blood. (Haematoxylin and eosin) $\times 170$.

Fig. 19, left below. Glomerulus, greatly enlarged. Most striking is the proliferation of the epithelial cells covering the capillary tuft and capsule; they form adhesions between the tuft and the capsule and often build small gland-like structures. The capillaries of this glomerulus contain a small amount of blood and there is an increase in ground substance and scattered hemorrhages into the capillary walls. (Haematoxylin and eosin) $\times 155$.

Fig. 20, right, below. Glomerulus. Most striking is the well-developed crescent of proliferating capsular epithelial cells. The capillaries of the glomerulus contain little blood. The walls of the capillaries are thickened by an increase in subendothelial ground substance. The epithelial cells covering the capillaries are large and show droplet degeneration. (Haematoxylin and eosin) $\times 155$.

DESCRIPTION OF CASES

CASE I J H H U 34614 T 534. Patient aged 40 years, colored 4 full term pregnancies, 1 living child Weight 174½ pounds.

The patient was seen at age 33 years, at which time she was 7½ months pregnant. The blood pressure was 100/100, the urine contained 0.8 gram albumin (Esbach). She was admitted for study but left the hospital against advice and was delivered elsewhere of a stillborn fetus. At age of 35 years she returned in labor with a blood pressure of 250/130 and delivered spontaneously.

At age of 40 years, she returned, not pregnant, complaining of pain in the stomach swelling of the legs, and difficulty in getting the breath. Patient stated that her father had died of 'bladder trouble' and her mother of kidney trouble. Her blood pressure was 148/96, eyegrounds showed marked vascular retinitis, bilateral. The phenolsulphonphthalein test showed less than 5 per cent excretion in first and second hour. The non protein nitrogen of the blood was 20.8 milligrams per cent and the uric acid 9.8 milligrams per cent. The urine contained one plus albumen, 1 to 3 white blood cells per high power field and no red blood cells. The blood pressure rose after admission to 262/160 millimeters mercury and the patient died. Clinical diagnosis chronic nephritis with terminal uremia.

Autopsy showed generalized arteriosclerosis arteriosclerotic nephritis necrosis in the pancreas cardiac hypertrophy and fatty heart chronic passive congestion of the lungs and lobular pneumonia.

Microscopic examination of kidney The normal architecture of the kidney is almost completely lost. The cortex and medulla are poorly demarcated and the surface is finely granular. There is a chronic process involving the vessels, glomeruli, and tubules which has led to considerable and diffuse sclerosis of the cortex. Superimposed on this is an acute destructive lesion of the vessels and glomeruli with hemorrhage throughout the walls of the small vessels, and capillary dilatation within the glomeruli. There are in places, extensive hemorrhages into the capsular spaces. These histological changes constitute a classical example of well advanced malignant nephrosclerosis. A description of the finer details of this case will serve as a standard for the others of its class to be described.

Vessels The entire arterial tree shows marked hypertrophy of the vessel wall (Fig. 1). In the interlobar, arcuate and larger branches of the lobular arteries the media is thickened and well preserved. There is a connective tissue thickening of the adventitia and of the intima. In the latter is seen a well developed lamellar elastosis (Fig. 2).

The smaller lobular arteries and the afferent vessels to the glomeruli show replacement of their muscular media by connective tissue. Three important changes in the intima are also seen. The most common is the endarteritis obliterans in which the thickened intima appears as concentric rings of cells and intercellular substance which frequently produces an

apparent occlusion of the lumen (Figs. 4, 5, 6, 7, 8, 9). Another lesion is the presence of a variable quantity of a poorly differentiated ground substance beneath the endothelium (Fig. 10). Finally, and most striking there are fresh hemorrhages throughout the vessel walls (Figs. 11, 12).

Glomeruli More than 90 per cent of the glomeruli are still moderately well preserved. They are larger than normal slightly more cellular, decidedly anemic and show an increase in the basement membrane and subendothelial ground substance. Superimposed on these changes are the fresh lesions so characteristic in the glomeruli of malignant nephrosclerosis. There are aneurismal dilatation of the capillaries, rupture of the basement membrane, and extensive hemorrhages into the capsular space and tubules (Figs. 13, 14, 15, 16). In glomeruli in which this lesion is somewhat older are seen proliferation of both endothelial and epithelial cells (Figs. 17, 18, 19, 20) and in still older lesions, an organizing process with sclerosis and adhesions between the tuft and the capsule.

A few scattered glomeruli are acellular and show hyaline transformation. The epithelial cells covering the glomerular tufts are frequently seen to be swollen with hyaline droplet degeneration.

Tubules The changes in the tubules are much more marked than those in the glomeruli. Those still recognizable as well differentiated proximal convoluted tubules are only occasionally seen and then usually in small islands at the periphery of the cortex. The great majority of the tubules are small, atrophic and collapsed. Many have disappeared entirely. The epithelial cells lining the tubules show degenerative changes and desquamation. Within the lumina are red blood cells, polymorphonuclear leucocytes, cellular debris, and precipitated protein.

Stroma There is a diffuse increase in the connective tissue stroma which occasionally shows a focal lymphocytic infiltration.

Adrenal and pancreas The changes in both large and small vessels of the adrenal and pancreas are similar to those already described in the kidney, although the lesions are less striking. The pancreas shows, in addition, areas of pancreatic necrosis.

The most striking changes in the kidney are those of the vascular tree. There is the vascular hypertrophy, the intimal elastosis, the proliferating endarteritis and the hemorrhage and necrosis of the walls. The tubules show widespread atrophy and disappearance, and present a striking contrast to the large number of fairly well preserved glomeruli. The latter show the increase in size and anemia so commonly seen in malignant nephrosclerosis, also the acute lesions—hemorrhage into the tuft and the walls of the capillaries of the tuft, and into the capsular space. These lesions are characteristic of malignant nephrosclerosis.

CASE 2 J H H U 30132 T 542 Patient aged 24 years, colored, has had 1 pregnancy at term, 1 abortion, 1 living child. At age of 17 years she had a soft chancre. Physical examination at that time revealed no other abnormality. Wassermann was negative. At age of 21 years she was admitted at 8½ to 9 months pregnant. Her mother died of "jaundice" her father of heart trouble. Blood pressure was 120/140. Urine showed an occasional granular cast, albumin, a faint trace and many white blood cells. Blood non-protein nitrogen was normal. Uric acid was 5.1 milligram per cent. Eye grounds showed "retinal edema." The blood pressure fell quickly after delivery and at discharge was 115/90.

At age of 22 years, patient returned 4½ to 5 months pregnant. Blood pressure was 120/130. Urine was negative for albumin. Eye grounds showed retinal edema. Urea clearance was 74 per cent. On observation with bed rest the blood pressure fell to 124/88 and patient was discharged. She was readmitted one month later. Blood pressure was then 170/130, eye grounds were normal, the urine negative. Hysterotomy and tubal sterilization were done. Six weeks after operation, blood pressure was 160/100, urine negative.

Six months after operation, patient was readmitted for study. Blood pressure on admission 103/155 fell to 160/105 on discharge. Examination showed blood chemistry and urine normal. Eye grounds showed retinal edema.

One year after operation, blood pressure was 155/180 and the patient complained of "dizzy spells." Interval blood pressures were about of this level.

The patient was readmitted at age of 24 years, complaining of headaches, dyspnea, and blurring of vision. Blood pressure was 2 0/130 urine albumin faint trace. Eye grounds, renal refinitis and arteriosclerosis. Phenolsulphonphthalein test 2 hour excretion was 35 per cent. Menses test, fixed specific gravity, urine occasional red blood cell and white blood cell.

She was discharged but readmitted shortly thereafter with a blood pressure of 240/160, complaining of dyspnea and showing evidence of cardiac decompensation. Eye grounds showed retinal hemorrhages. Urine contained many white blood cells, occasional red blood cells and casts. The patient died on the fourth day. Clinical diagnosis chronic cardiovascular renal disease.

Autopsy report was not available.

Microscopic examination of kidney. Here, too the architecture of the cortex is greatly altered as a result of the atrophy and disappearance of the tubules in some areas and their dilatation and elongation in others. The vessels show the same lesions as in Case 1 but these are more frequently seen and more severe. One of the striking features is that the few remaining well differentiated proximal convoluted tubules are localized in areas at the very periphery of the cortex and resemble in this regard, the zones of healthy tissue seen in Case 5.

Arteries. The lesions in the vascular tree are as described in the standard Case 1. Hemorrhage and saturation with plasma of the walls of the smaller vessels is commonly seen (Figs. 11-12). In the lobular arteries, these fresh lesions are largely limited to the intima and the elastic lamina appears stretched but unbroken. These changes may frequently be traced to the corresponding glomerulus which shows in turn a similar change (Figs. 13, 14, 15, 16). There are older lesions in which the fibrin in the wall of the small vessels shows organization, and granuloma-like formations are seen along the afferent arterioles (Figs. 17-18). The endothelium of these small vessels is swollen and shows proliferation. Fibrin thrombi occasionally obstruct the lumina.

Glomeruli. The glomerular lesions are typical of those seen in malignant nephrosclerosis. The proportion of glomeruli in a state of reasonable preservation to those which have been destroyed and have become hyaline is as in Case 1. The same changes in the relatively intact glomeruli are seen. In some of the afferent arterioles there is seen what appears to be a very recent aneurysmal dilatation where the vessel enters the glomerulus (Fig. 16). There is hemorrhage into the walls of these vessels and into the capsular space while the capillaries of the tuft are dilated (Figs. 13, 14, 15).

Tubules and stroma. These show the same changes as those described in Case 1.

Pancreas and adrenal. The arterioles of both organs show hyaline thickening of the media. The small vessels show by all transformation of their walls. The arterioles of the pancreas show in addition, plasma beneath the endothelium although this is not frequently found.

The lesions in this case are similar in every respect to those described in the standard case. The histological findings suggest that the process has been the most severe of the group.

CASE 3 J H H U 18567 T 535. Patient aged 36 years, colored, has had 5 term pregnancies, 3 abortions, 5 living children. At age of 31 years she was observed throughout a pregnancy. The systolic blood pressure reached 155 millimeters mercury and the diastolic 106 millimeters mercury. The urine was negative throughout. The weight 151 pounds. At age of 32 years she was observed during another pregnancy. Highest systolic blood pressure was 150 millimeters mercury highest diastolic 112 millimeters mercury. Urine was negative throughout. The weight reached 16 pounds. At the age of 34 years she again became pregnant and was admitted at the sixth month. Blood pressure was 214/170, urine contained two plus albumin weight was 170 pounds. After admission the blood pressure rose to 236/174. Phenolsulphonphthalein test showed 22 per cent in first hour 13 per cent second hour. "Marked retinal arteriosclerosis and arteriosclerotic retinitis." There was edema of the extremities, urine contained albumin 2-3 plus, fine granular casts and red blood cells.

The patient aborted spontaneously. She was seen 2 year later, not pregnant, blood pressure 210/150, urine, albumin 2 plus. One year after this a blood pressure of 224/170 was recorded.

At age of 36 she again became pregnant and was admitted at 3 to 4 months. Blood pressure 200/140. Phenolsulphonphthalein test, 35 per cent excreted in first hour, 20 per cent second hour. Blood non-protein nitrogen was normal. Urine showed albumin 3 plus with fine granular casts and red blood cells. The patient was sterilized by hysterectomy. Six weeks later blood pressure was 200/150 urine albumin 1 plus. Four weeks later blood pressure was 210/170.

Eight months post abortum the patient was admitted, not pregnant, complaining of headaches and bloody urine. Blood pressure was 258/198 phenolsulphonphthalein test, 8 per cent in 2 hours. Non-protein nitrogen of blood 85.6 milligrams per cent. The 24 hour urine volume varied between 400 and 600 cubic centimeters. The patient died. Clinical diagnosis chronic nephritis.

Autopsy showed chronic arteriolosclerotic nephritis cardiac hypertrophy with myocardial scarring lobular pneumonia, slight perivascular mononuclear infiltration in the medulla slight arteriosclerosis of aorta adenomata of thyroid hypophyseal duct cyst with a tropic changes in the hypophysis.

Microscopic examination of kidney The kidney architecture is moderately well preserved although there is a diffuse increase in the connective tissue throughout the cortex and fine granulation of the surface. The vessel changes are characteristic of malignant nephrosclerosis.

Vessels Lesions are similar in all respects to the standard Case 1.

Glomeruli Most glomeruli are fairly well preserved. The most striking lesions are the recent degenerative and inflammatory changes. These present an accumulation of ground substance between the endothelium and the basement membrane producing apparent complete occlusion of the lumen of the capillaries. In these glomeruli the endothelial cells are increased in number and the overlying epithelial cells show marked swelling droplet degeneration, and proliferation. These cells are found continuous with those of the capsular wall (Fig. 19). There are no aneurysmal dilatations although occasionally red blood cells are found within the capsular space.

Tubules and stroma. The lesions here are as described in Case 1 although in this case a greater number of tubules retain their differentiation.

Pancreas There is hypertrophy of the media of the larger arteries sclerosis and hæmorrhage into the wall are seen in the smaller arterioles. In general the lesions are similar to those seen in the vessels of the kidney although of lesser degree.

Again the most striking lesion is that of the arterial tree of the kidney. The changes in the glomeruli and tubules are not far advanced

and are largely degenerative. The changes are typical of those described in malignant nephrosclerosis, although the lesions in this case are not so advanced as in Cases 1 and 2.

CASE 4 J.H.H.U. 29163 T 539 Patient aged 37 years, colored had had 4 pregnancies at term 2 abortions, 4 living children. Her weight was 119 pounds. At age of 35 years, not pregnant, blood pressure was 288/140 Wassermann was negative. Family history was negative. At age of 36 years she was admitted to hospital 5 months pregnant. Blood pressure was 230/160 moderate cardiac hypertrophy no abnormal symptoms. Eyegrounds normal save for attenuation of arteries. Phenolsulphonphthalein test showed 15 per cent first hour 25 per cent second hour. Urine revealed a trace of albumin otherwise negative. Therapeutic abortion and sterilization were done. On discharge, blood pressure was 160/115 urine, negative.

The patient was observed frequently following this. The blood pressure continued at about the level of 230/150 and the urine remained negative. She complained of occasional headaches.

At age of 37 years she was admitted not pregnant. Blood pressure was 240/150 Eyegrounds showed moderate arteriolosclerosis without hæmorrhages or exudates. Blood non-protein nitrogen was 57.8 milligrams per cent. Blood uric acid 7.2 milligrams per cent. Urea clearance test 7.5 per cent. Urine showed occasional white blood cells and granular casts albumin 3.5 grams (Esbach). The patient died. Clinical diagnosis chronic nephritis.

Autopsy showed chronic nephritis with hæmorrhages cardiac hypertrophy, subendocardial hæmorrhages fat in myocardium cystitis lobular pneumonia.

Microscopic examination of kidney The lesions in the component parts of the kidney are very similar to those in Case 3. The lesions are typical of those described as malignant nephrosclerosis but the severity of the lesions in this case is the least of those described in this series.

The vessels present the same picture as that in the standard Case 1. Fewer glomeruli are anæmic and fewer have undergone hyaline degeneration. There is no marked capsular change, and adhesions are rare. The majority of the tubules are still well differentiated although granular and droplet degeneration are common.

The striking lesion, again is in the arterial tree of the kidney and both chronic and fresh lesions may be recognized. The tubules in general are moderately well preserved. Only kidney tissue was available for study.

Two cases showed variations from those described as typical of malignant nephrosclerosis. The first of these Case 5, shows an exaggeration of the usual lesions with an added

infarction of the cortex. It presents the most severe form of the lesions seen in this series. A description of this case is followed by that of Case 6 which may be placed at the opposite end of the list. It represents a transitional stage between malignant nephrosclerosis and the lesions of what has been described as benign nephrosclerosis. The histological findings are similar to those of malignant nephrosclerosis but are of a mild degree in comparison with the typical picture as described above.

CASE 5. J.H.H. 51 T 533. Patient aged 35 years, colored, had had 8 full term pregnancies, premature labors, 1 abortion, 6 living children. There are available records of 4 previous pregnancies. At the age of 20 and 26 two pregnancies were normal. At 28 years a pregnancy was complicated by a blood pressure of 170 millimeters mercury as highest systolic and 95 millimeters mercury as highest diastolic. There was a moderately severe preclampsia of short duration. In the pregnancy went to term and ended spontaneously. At 29 years there was another term pregnancy with highest systolic blood pressure of 145 millimeters mercury and highest diastolic of 100 millimeters mercury. The urine was negative throughout. The Wassermann was also negative. The patient said that her mother had died of dropsy.

The present pregnancy ended in the spontaneous abortion of a 5 to 6 month fetus elsewhere. The patient had suffered throughout pregnancy from "dim vision and a sense of weakness." Interference with vision became more marked postpartum and the patient was admitted. The findings on admission were blood pressure 156/110, temperature 98.6 degrees F, urine albumin 4 plus, specific gravity 1.033, no casts or red blood cells. External ocular muscle movements were poorly performed. The following day the patient showed twitching of the right arm and leg. The blood pressure had risen to 170/144, hemoglobin 35 per cent, and there was a leucocytosis of 20,20. Phenolsulphonphthalein test showed no excretion in either the first or second hour and the non-protein nitrogen of the blood was 162.5 milligrams per cent. On successive days the non-protein nitrogen of the blood rose to 240 and 35 milligrams per cent. The Wassermann reaction was negative. The patient died. Clinical diagnosis chronic nephritis with cretinism.

Autopsy showed "puerperal uterus with infection chronic diffuse nephritis with necrosis and thrombosis of the arterioles. Infarctions of the kidney multiple necroses of the pancreas hyperplastic bone marrow alteration of the spleen oedema of the lungs with slight lobular pneumonia."

Microscopic examination of kidney. The normal architecture of the kidney is greatly distorted. The cortex and medulla are not sharply demarcated and the cortex lacks an orderly arrangement. The sur-

face is pitted. There are two outstanding lesions. The first and more spectacular is the presence of recent scattered infarcts in the cortex. The other is a more chronic process with sclerosis of the medium sized and small vessels apparent obliteration of the intima of these vessels, and widespread atrophy of the cortex with streaks of fibrosis of its stroma. These areas of fibrosis frequently present a triangular outline with the base at the peripheral portion of the cortex. As a result of these lesions there is very little well preserved cortical parenchyma.

Arteries. The interlobular arcuate and lobular arteries are all of unusually large diameter. The media in the larger of these is not only thickened but well preserved. The adventitia and intima are also thickened with reduplication of the internal elastic lamina of the latter. In spite of this increase in the thickness of the walls of the larger arteries the lumina are still larger than those of the corresponding vessels of the normal kidney.

The changes in the smaller vessels are similar to those described in the typical cases of malignant nephrosclerosis. Similar changes are seen even in some of the larger lobular arteries (Fig. 3). Fibrin thrombi are frequently seen and the replacement of the muscular media by connective tissue is marked. The smaller vessels are unusually tortuous. The intima of the vessel walls is also exaggerated in degree and frequency. Plasma may be seen in all layers, and red blood cells and occasional polymorphonuclear leucocytes are found within the walls and may even be traced into the surrounding stroma. This is often associated with thrombosis of the lumen of the vessel.

Glomeruli. The glomerular changes are similar to those described with the typical cases except that they tend here to be obscured by the presence of fresh areas of ischemic necrosis.

Tubules. These also present the changes described as typical, with the additional factor as in the glomeruli. Many are filled with red blood cells, broken-down, desquamated cells and hyaline and granular casts.

Stroma. The older lesions are characterized by an increase in connective tissue and an infiltration with lymphocytes. The fresh lesions show oedema and hemorrhage.

Vessels and capillaries. The interlobular capillaries and veins are moderately distended but no histological change can be recognized.

Basement membrane. Due to the marked increase in subendothelial ground substance and the secondary organization, the basement membrane of the small arteriole is often difficult to trace. Occasionally it appears to be interrupted and bathed in plasma. In the glomerular tuft it is often wrinkled, thickened, and reduplicated.

Adrenal. The small arteries in the capsule show only hypertrophy of the media whereas in the small arterioles in the medullary portion there is hyaline swelling of the basement membrane without necrotizing arteriolitis such as is seen in the kidney.

The lesions seen here are an exaggeration of those described in the typical case. The chief lesion is that of the arterial tree in the kidney. The vascular hypertrophy, arteriosclerosis, and arterionecrosis are characteristic of malignant nephrosclerosis. This necrosis is so extensive and so frequently associated with thrombosis that it is not surprising to find many areas of ischemic necrosis of the cortex. There is then a chronic process involving the vessels glomeruli and tubules. Superimposed upon this, is recent vascular damage with necrosis of the vessel walls thrombosis and in fact formation.

This case is similar to a group described by Von Zalka (1932-1933) under the term "symmetrical cortical necrosis of the kidney." His cases were more advanced and the necrosis more widely spread. They showed either a massive necrosis or multiple infarcts of the cortex but never with involvement of the medulla. He described hyalinization of the lobular arteries, afferent arterioles, and glomeruli with fibrous thrombi in the lumen. In his own case he speaks specifically of vascular necrosis. Altogether the condition which he describes has a marked resemblance to that in the present case, although in his opinion he was not dealing with malignant nephrosclerosis.

What is equally important from the point of view of the present discussion is that he recognized the relation of "cortical necrosis" to pregnancy. He states that of 37 cases collected from the literature 31 were possibly related to pregnancy. Three, however, occurred in males and three more were not related to pregnancy. This is the closest approach to a recognition of the relation between the vascular changes described in this paper and the toxemias of pregnancy which a search of the literature has brought to light.

CASE 6 J.H.H.U. 8662 T 531 Patient aged 29 years, colored, 6 previous pregnancies, 1 abortion and 2 living children. The first child was stillborn. The second and third are alive and well. The last three pregnancies produced stillborn children and in the last of these pregnancies the patient is said to have had convulsions. When first seen there was a pregnancy of 2½ to 3 months' duration. The heart was enlarged to clinical examination, the blood pressure 208 millimeters mercury systolic and 110 milli-

mmeters mercury diastolic. The weight was 218 pounds. The urine contained a moderate amount of albumin. The patient was admitted 2 days later when the blood pressure was found to be 256/140 the urine contained albumin occasional leucocytes, and some cellular casts. Specific gravity was 1.011. Mosenthal test showed a fixation of specific gravity of 0.0010 but a varied quantity and a large night volume. Blood non protein nitrogen was 42.8 milligrams per cent. A hysterectomy was done. Three days after operation the non protein nitrogen of the blood had risen to 120 milligrams per cent and some granular casts and some red blood cells appeared in the urine. The patient died on the eighth day after operation. Clinical diagnosis peritonitis chronic nephritis with uremia.

Autopsy showed suppuration of the abdominal incision, purulent pelvic peritonitis, early generalized peritonitis, chronic nephritis and moderate arteriosclerosis.

Microscopic examination of kidney. There is considerable change from the normal architecture of the cortex, with some reconstruction. The surface is irregular and there is moderate scarring in the form of irregularly interlacing paths of connective tissue. The most striking lesion is seen within the arterial tree. This shows a vascular hypertrophy and a sclerosis of the small arterioles. The interlobar the arcuate and the first portions of the lobular arteries show a dilatation of their lumina, a thickening of the muscular media and, here and there a reduplication of the internal elastic lamina. The distant portions of the lobular arteries and the afferent arterioles to the glomeruli show in contrast a rather striking group of changes. These vessels are tortuous, the muscular media is replaced by connective tissue, and the subendothelial ground substance is increased to such an extent as to cause in places apparent complete occlusion of the lumen. Less commonly, small granuloma like formations are seen along the vessels where they approach the glomeruli.

Most of the glomeruli are moderately increased in size and show a slight increase in the number of cells. The basement membrane itself is unchanged but the overlying epithelial cells are swollen and show hyaline droplet degeneration. The epithelium lining the capsule is also swollen and the cytoplasm shows similar regressive changes. The basement membrane of the capsule is unchanged. A relatively small number of glomeruli, in large measure confined to the areas of cortical scarring, are small, contracted and acellular and show complete hyaline transformation. Occasional adhesions between the glomerular tuft and the capsule are seen.

There remain a moderate number of easily recognizable tubules appearing usually in the form of islands bordered by tracts of scar tissue. The lumina are dilated and contain little precipitated protein. The lining epithelial cells are cuboidal with indistinct cell boundaries. The cytoplasm shows both granular and droplet degeneration. The basement membrane is unchanged. In contrast to these are

the changes seen in the tubules in the areas of sclerosis. These are small collapsed and their narrowed lumina contain minute hyaline casts. The basement membrane of these is thickened, wrinkled reduplicated, and there is occasionally an acellular ground substance between these double layers of basement membrane. In the lumina of some of the collecting tubules are granular deposits of hemoglobin.

In the areas of tubular atrophy there is an increase in connective tissue. This is infiltrated with lymphocytes and frequently shows a well developed lymphoid tissue in which reticulum is clearly recognizable.

Pancreas and adrenal. The large and small arteries of the adrenal and pancreas show much the same changes as those described in the kidney. There are hypertrophy of the media of the larger vessels and intimal sclerosis with occlusion of the smaller arteries. The larger vessels show enlargement of their transverse diameter. The smaller show hyaline degeneration of the entire wall but neither necrosis nor hemorrhage. The lesions here may be described as those of arteriosclerosis.

The type of the vascular change is characteristic of neither benign nephrosclerosis with its hyaline swelling of the basement membrane nor of malignant nephrosclerosis with its interruption of the basement membrane and saturation of the wall with blood and plasma. It apparently represents a transitional stage. The tracts of sclerosis within the cortex correspond to the distribution of the more severe vascular lesions. The degenerative changes in the epithelium of the glomeruli and tubules are apparently recent and may be considered as a mild glomerulo-tubulo-nephrosis. This is in contrast to the older vascular lesions. The patient died with peritonitis presumably before the lesions of malignant nephrosclerosis had had time for complete development.

These cases have a number of features in common. The condition occurs in relatively young women usually between 30 and 40 years of age. All have become pregnant in the presence of hypertensive disease which has been adversely affected by the pregnancy. In many the original hypertensive disease appeared during the course of a toxemia of pregnancy. After a varying period of time during which hypertension was the only feature common to all there was a sudden appearance of other symptoms referable to both the cardiovascular and urinary systems and the patients quickly thereafter died. Death in all cases was shown to be associated with uremia.

Pregnancy occurring in the presence of a hypertension or of a chronic nephritis following a pregnancy toxemia seems to play an important rôle in the production of the acute lesions of malignant nephrosclerosis. The degree of the interval hypertension and its duration are also determining factors. It must be stressed that all of these had had a hypertension of some duration. As will be seen later none of the cases in which death occurred during a toxemia with hypertension for the first time showed the vascular lesions within the kidney of malignant nephrosclerosis, although in patients dying with eclampsia vascular lesions may be found within the liver identical with the acute lesions of malignant nephrosclerosis.

The microscopic examination shows the most striking lesions to be in the vascular system. These are best seen in the kidney but may also be recognized in the vessels of other organs. They show clearly a chronic condition manifested by hypertrophy of the larger and smaller arteries of the vascular bed. There is an hypertrophy of the muscular media and thickening of the adventitia. The total diameter of an artery and that of the lumen is greatly enlarged. Superimposed upon this are other lesions in the small arteries and arterioles and in the glomeruli tubules and stroma. These are characterized by

1. Thickening and hypertrophy of the intima of the arterioles with frequent apparent occlusion of the lumina (Figs. 4 5 6 7 8 9 10)

2. Saturation of the wall of the smaller vessels with blood plasma and red blood cells (Figs. 11 12)

3. Damage to scattered groups of glomeruli. These changes include aneurysmal dilatation of the walls of the afferent arterioles after they have entered the glomerulus, saturation of their walls with plasma and red blood cells, and hemorrhage into the glomerular capsule and proximal portions of the tubules. The finer histological changes have been described above (Figs. 13 14 15 16)

4. Destruction of the tubules and increase in the connective tissue stroma of the cortex. Small islands of dilated tubules remain at the periphery of the cortex

These are the lesions described as those of malignant nephrosclerosis. It is significant that every patient who fell into this clinical group showed the same histological picture. The question naturally arises as to whether or not all patients who have residual damage in the form of obstetrical chronic nephritis following a pregnancy toxæmia and who later die with clinical symptoms of uræmia will show the same clinical and histological picture. This cannot be answered by the present study. It should be pointed out, however, that the cases described above together with those which follow, make up all of the material which it was possible to obtain from the obstetrical service records of Johns Hopkins Hospital. The chance of sampling error is inherent in the study of such small groups but no other element of choice has interfered.

A further group of 5 cases died with a clinical diagnosis of nephritis. It will be seen at once that these differ from the malignant nephrosclerosis group since in none of them is there a history of hypertension before the present pregnancy.

CASE 7 J H H U 13203 T 540 Patient was 27 years of age, white and had had 2 term pregnancies with no living children. At 23 years of age a pregnancy was observed during which blood pressures of 110/86 and 122/92 were recorded. On admission at term, the urine contained albumin 2 plus and a few hyaline casts.

At 27 years of age patient was seen when 3 to 4 months pregnant. Blood pressure was 148/100. The urine showed a trace of albumin. She was admitted for study. The eyegrounds showed moderate retinal oedema, moderate arteriosclerosis. Urea clearance was 86 per cent. Highest blood pressure was 162/115. Blood chemistry analysis revealed normal findings. The blood pressure fell and she was discharged. The blood Wassermann was positive but we have no record of treatment. She was readmitted 2 months later complaining of dizziness. The blood pressure ranged about 150/100, the urine was negative, the weight 124½-109 pounds. There developed oedema generalized and in the lungs dyspnoea and orthopnoea. The patient died, undelivered, 2 months after admission, with a diagnosis of chronic nephritis, arteriosclerosis, and cardiac decompensation.

Autopsy report showed "heart hypertrophied with hypertrophic musculature and old scars, arterioles reveal hyaline changes in kidney and pancreas intracapillary and glomerular changes in the kidney lungs, chronic passive congestion liver, slight catarrhal atrophy cells beneath capsule of

liver and in lung capillaries which closely resemble chorionic cells, liver patchy areas of dilated sinusoids surround areas in which the liver cell capillaries show what appear to be fibrin thrombi. It resembles the liver of eclampsia but the lesions are mid zonal.

Microscopic examination of kidney The normal architecture of the kidney is well preserved. The one striking pathological finding is a degenerative change in the epithelium of the glomerulus and tubules. These cells are remarkably swollen and granular. The lumina are almost obliterated, although precipitated albumin and haemoglobin casts may be seen. The vessels and stroma show no pathological change.

Pancreas and adrenal The vessels in these organs show no lesions.

The findings here are those of glomerulo-tubulo-nephrosis and the histological lesions are similar to those of the eclamptic nephrosis.

CASE 8 J H H U 40316 T 536 This woman aged 33 years, colored, had had 4 term pregnancies, 4 living children. All of these were delivered elsewhere and there were no available observations until the patient was admitted about 8 months pregnant complaining of swelling of the hands and feet and blurring of vision of 3 weeks duration. Blood pressure was 230/160. Urine albumin 1+5 grams (Esbach) showed numerous red blood cells, white blood cells, and occasional fine granular casts. The eyegrounds showed advanced renal retinitis with moderate arteriosclerotic changes and some neuroretinitis. Blood non protein nitrogen was 41 milligrams per cent. Blood uric acid was 8 milligrams per cent. A caesarian section was done. Blood non protein nitrogen rose to 57.8 milligrams per cent and uric acid to 11.4 milligrams per cent. The patient died on the second day after operation. Clinical diagnosis chronic nephritis.

Autopsy showed "fatty kidneys containing much fat, old scars and cyst in right kidney, dilated right ureter containing pus, hemorrhage in adrenal, myocardial hypertrophy, hemorrhages beneath the endocardium.

Microscopic examination of kidney The normal architecture is well preserved. There is marked swelling of the tubular epithelium with granulation of its cytoplasm. The glomerular capillaries contain blood. The epithelium covering the tuft is slightly swollen. The vessels and stroma are unchanged.

Pancreas and adrenal Both large and small vessels show no pathological findings.

The histological diagnosis is acute tubular nephrosis without vascular change.

CASE 9. J H H U 12058 T 543 This woman aged 39 years, white, had had 4 term pregnancies, 1 abortion, 4 living children. All pregnancies were observed elsewhere. When first seen the patient

was at term, blood pressure 220/140. Urinalysis showed albumin 4 grams (Esbach). She was admitted at once and labor induced by means of a bag. Delivery was accomplished by version and extraction under chloroform anesthesia and was followed by a postpartum hemorrhage of 1200 cubic centimeters with some evidence of shock. The patient died on the same day. Clinical diagnosis pre-eclamptic toxemia, postpartum hemorrhage and shock.

Autopsy showed history of manual delivery hemorrhage and shock postpartum uterus containing blood clot bilateral tears of the lower uterine segment and cervix chronic nephritis petechial hemorrhages of heart and skin of lower extremities old mitral endocarditis focal necrosis of liver.

Microscopic examination of kidney. The normal architecture is well preserved. The important pathological lesion is degeneration of the tubules with swelling of the epithelium and narrowing of the lumen. In an occasional tubule the cells show necrosis and calcification. The glomeruli show little change and the vessels and stroma show none.

Pancreas and adrenal. These show little change although there is enough hyaline transformation of the arteriolar walls of the pancreas to allow a diagnosis of slight arteriosclerosis.

The changes here are those of a tubular nephrosis in the acute stage. The arteriosclerosis in the pancreas is so slight as to be negligible.

CASE 10 JHHU 7588 T 538. This patient aged 25 years, colored, had had no previous pregnancies. She was admitted 7 months pregnant. There was a history of occasional hemoptysis. A right sided pyelitis was found with pyuria. The urine contained staphylococci but no tubercle bacilli. Temperature remained normal throughout. The urine contained many white blood cells, a few red blood cells, and albumin 3 plus. No blood pressure readings were taken. Spontaneous labor yielded a stillborn premature fetus. The placenta was diagnosed as syphilitic. The patient died. Clinical details are lacking.

An autopsy report on this patient was not available.

Microscopic examination of kidney. The normal architecture of the kidney is slightly distorted through an irregularity in the arrangement of the tubules. These show degeneration but also regeneration in areas where cells have been destroyed. Within the lumina of the tubules may be seen red blood cells, polymorphonuclear leucocytes, fibrin and precipitated protein, with scattered desquamated epithelial cells. The surrounding stroma in these areas of regeneration is slightly increased and edematous and shows a fairly rich infiltration with inflammatory cells. Neither vessels nor glomeruli show significant changes.

Pancreas and adrenal. The arteries and arterioles show no pathological changes.

This case shows the characteristics of a tubular nephritis. There are no vascular changes.

CASE 11 JHHU 5911 T 541. Patient aged 40 years, had had 2 abortions. When first seen, she was 8 months pregnant. The urine contained 3 grams of albumin (Esbach) specific gravity 1.018-1.020, moderate number of granular casts. Hemoglobin was 42 per cent. Blood pressure was 170 millimeters mercury systolic. A placenta previa was diagnosed and delivery by cesarean section at term under chloroform anesthesia was carried out. The patient died on the sixth day after operation. Clinical details are lacking.

Autopsy showed "acute endometritis acute diphtheritic colitis hemoperitoneum fatty degeneration of the liver chronic diffuse nephritis chronic adhesive pleurisy perihepatitis and perisplenitis."

Microscopic examination of kidney. The normal architecture of the kidney is preserved. There is granular degeneration of the epithelium of the tubules. They are dilated and contain large quantities of precipitated protein and casts. The glomeruli show some swelling of the epithelium. There is muscular hypertrophy of the vessels which is most marked in the larger stems. The stroma is essentially unchanged although there are minute foci of sclerosis and of lymphocytic infiltration.

Pancreas and adrenal. The arteries and arterioles show no pathological changes.

This, Case 11 is a tubular nephrosis with vascular hypertrophy.

Cases 7, 8, 9, 10 and 11 represent the clinical and pathological picture of toxemias of pregnancy occurring for what is presumed to be the first time. They all show the lesions characteristic of that condition. What is more important from the point of view of this study is that none shows the lesions of malignant nephrosclerosis. Case 11 and 10 to a much lesser degree, Case 9 with vascular hypertrophy might be considered as potential malignant nephrosclerosis in whom the time interval and the degree of damage were not yet sufficient for the development of the typical lesions.

For the sake of completeness two further cases are given brief description.

CASE 12 JHHU 6320 T 537. Patient, colored, aged 38 years, had had no pregnancies. She had typhoid at age of 18. At age of 28 years, not pregnant, blood pressure was 174/130. At age of 29 years, not pregnant, blood pressure was 134/88. At age of 32 she was first seen when 6½ months pregnant. Blood pressure was 190/120 and 170/110. Urine was negative for albumin. Four days later blood pres-

ure was 150/110. Eyegrounds were normal. Phenolsulphonphthalein test showed 55 per cent excretion first hour 10 per cent second hour. Patient complained of vomiting. Sixteen days later she was still vomiting and blood pressure was 130/86. The pulse rose to 140-150 and blood pressure of 140/108 was recorded. Patient aborted a 9 months stillborn fetus. Throughout this time the blood non protein nitrogen was normal. The patient died. Clinical diagnosis chronic nephritic toxæmia.

Autopsy report not available but a note was made by an observer from the obstetrical service to the effect that the right kidney showed marked destruction of the substance with multiple abscesses, no dilatation of pelvis of right kidney, left kidney showed many hemorrhagic areas and a few abscesses, few patches of broncho-pneumonia.

Microscopic examination. The kidney showed typical lesions of malignant nephrosclerosis. No abscesses were present. The vessels of the pancreas showed only hypertrophy of the media. The adrenal showed hypertrophy of the arteries of the capsule with marked arteriosclerosis and hemorrhage into the walls.

The lesions here are typical of malignant nephrosclerosis. The original damage was not associated with pregnancy since death occurred following the first of these. The pregnancy was however, implanted upon a pre-existing hypertension.

This case is not included in the consideration of the group of malignant nephrosclerosis for the reason that the observation of abscesses in the kidney was reported and none was found on microscopic examination. That it belongs in the group is reasonable to suppose but the uncertainty of identity has demanded a separate report.

CASE 13 J.H.H.U. 36650 T 532 This woman, aged 39 years, colored, had had 5 term pregnancies, 4 living children. At age of 13 years a term pregnancy was observed. The urine at one time contained $\frac{1}{4}$ gram albumin (Esbach). No further data. At age of 25 years term pregnancy, no data. At age of 26 years term pregnancy, blood pressure and urine normal.

At age of 29 years, term pregnancy, two blood pressures of 135/90 and 140/100 were recorded. Urine albumin trace once.

At age of 39 years, patient was admitted pregnant and close to term. She had complained of vomiting and headaches for 2 weeks. Two hours before admission she became comatose. Her mother had died of apoplexy. Eyegrounds, retinal edema bilateral. Blood pressure was 105/80. Urine showed albumin 4 plus, large numbers of red blood cells and white blood cells. Blood non protein nitrogen 103.5 milligrams per cent. Blood uric acid was 14.5 milli-

grams per cent. Hemoglobin was 16 per cent. white blood cells 15,000. red blood cells 920,000. A caesarean section with hysterectomy was done. The patient died 4 days later of septicæmia complications, chronic nephritic toxæmia of pregnancy.

Autopsy showed chronic cystitis and pyelonephritis organizing and fresh thrombi in the pelvic veins, multiple small emboli in lungs, confluent lobular pneumonia, acute splenic tumor, swollen liver with hydropic cells, hyperplasia of the bone marrow, multiple infected thrombi in the hypophysis with extensive necrosis, embolus in right middle cerebral artery, foci of fresh encephalomalacia with bacteria, local myocarditis, scars in myocardium, cholelithiasis, focal scars in liver.

Microscopic examination of kidney. Well preserved kidney showing moderate vascular hypertrophy. Superimposed upon this is a fresh degenerative and inflammatory reaction involving the tubules, glomeruli and stroma. Some of the capillaries of the glomeruli are filled with organisms. The tubules show granular and fatty degeneration of the cytoplasm of the epithelium. The stroma is edematous and contains polymorphonuclear leucocytes and lymphocytic exudate.

Pancreas. Vessels show no pathological change. There is a diffuse interstitial pancreatitis.

This patient died with septicæmia. As a result of this there is bacterial focal glomerulonephritis and simple tubular nephrosis with toxic edema of the stroma. There is also a mild simple arteriosclerosis with vascular hypertrophy which played no part in the fatal issue. Lesions of malignant nephrosclerosis are not present.

SUMMARY

1 The toxæmias of pregnancy frequently produce permanent vascular damage to the patient. Many of these women die in a short period of time. Statistical evidence of this from the literature is presented.

2 A clinical and histological study of all of the deaths indexed as from nephritis which have occurred on the obstetrical service of Johns Hopkins Hospital and from which pathological material was available is reported.

3 Two groups of cases have emerged (a) Those in which the patient died during or immediately following a pregnancy complicated by a non-convulsive toxæmia and in whom no history of previous hypertension was obtained showed tubulonephrosis and in no case, the characteristic lesions described as malignant nephrosclerosis.

(b) The second group is made up of those patients who have suffered from a chronic nephritic toxæmia of pregnancy. In every case the hypertension has preceded the last pregnancy and has existed for from 2 to 7 years before death. Every patient in this group was found to present the characteristic lesions of malignant nephrosclerosis as described by Volhard and Fahr (1914) and Fahr (1934).

We wish to take this opportunity to express our appreciation to Professor W. G. MacCallum of the Department of Pathology, Johns Hopkins Hospital, for permission to use the material here presented.

THE RECURRENT LARYNGEAL NERVES IN TOTAL ABLATION OF THE NORMAL THYROID GLAND

AN ANATOMICAL AND SURGICAL STUDY¹

DAVID D. BERLIN, M.D., F.A.C.S. BOSTON, MASSACHUSETTS

From the Surgical Service of the Beth Israel Hospital, Boston, and Department of Anatomy and Surgery, Tufts College Medical School

THE recurrent laryngeal nerves constitute the greatest technical hazard in total ablation of the normal thyroid gland. This procedure for the treatment of angina pectoris and congestive heart failure was recently advanced by Blumgart and his co-workers at the Beth Israel Hospital in Boston (5). Of a total number of more than 70 complete thyroidectomies 65 were performed for the relief of advanced cardiac disease and the encouraging results thus far achieved augur well for its useful application in angina pectoris and other forms of chronic heart disease. The operative technique and results have been reported elsewhere (2, 6).

The purpose of this communication is to call attention to the technical hazard of the recurrent nerve, pointing out its various vulnerable juxtapositions to the gland and thus to assist the surgeon in avoiding serious nerve injury with its consequent disastrous vocal cord complications. The extensive operation of removing the entire thyroid gland obviously presents a great risk of injury to the recurrent nerves. An accurate knowledge of the variations in the relationship of these nerves to the thyroid gland then is of vital assistance to the operator in the prevention of abductor paralysis. It is this variability of position rather than the vulnerability of the nerve itself that is responsible for the frequency with which it may be seriously injured.

ANATOMICAL DISSECTIONS OF THE RECURRENTS IN SEVENTY CADAVERS

During the past 2 years anatomical dissections were made of both recurrent laryngeal nerves in 70 cadavers. Particular study was made of the position of the nerve in relation to the thyroid gland and its adherent zone (Fig. 3h). In a previous communication (2) the latter area was described as an expression

of normal anatomy indicating the fixation of the gland to the trachea just below the antero-lateral aspect of the bar of the cricoid cartilage at the level of the first and second tracheal rings. The anatomical courses of the nerves were conveniently classified into three groups (Table I).

Group I The most hazardous position of the nerve in relation to the gland is shown in Figures 3c, 4a, 4b, and 5. Ten per cent, or 14, of a total of 140 nerves, were found partially penetrating the gland, 9 on the right side, 5 on the left. When encountered in this vulnerable position, the nerve is carefully dislodged by blunt dissection from its surrounding bed of glandular tissue.

Group II Approximately 25 per cent of the nerves were demonstrated traversing the adherent zone (Fig. 3h and 3d). 19 on the right and 16 on the left side. After mobilization of the corresponding lobe by the ligation and severance of the lateral thyroid vein and the vessels of the upper and lower poles, the adherent zone is brought into view. Subsequent traction on the lobe reveals the pronounced fixation of the gland to the trachea at this point. Frequently, the nerve is concealed in this region beneath a stratum of fibrofascial and fatty tissue. By careful exploration with a blunt instrument it is possible to identify and preserve the nerve uninjured.

Group III In our dissections, 65 per cent of the nerves were found coursing safely in the tracheo-esophageal sulcus, in which position the nerve is best protected against operative injury (Figs. 3a, 6a, and 6h). The classical anatomical textbooks in their description refer only to this position of the nerve, not mentioning either the possibility of partial penetration of the gland by the nerve or the important relationship existing between the nerve and the adherent zone.

¹This is the twelfth study of the treatment of chronic heart disease by producing a subnormal metabolic rate in patients with no evidence of thyrotoxicosis.

COMPARATIVE SURGICAL OBSERVATIONS OF THE RECURRENT LARYNGEAL NERVE IN SEVENTY TOTAL ABLATIONS OF THE NORMAL THYROID

Observations were made in a total number of 72 recurrent nerves in the course of 70 total thyroidectomies. Table II demonstrates the different positions occupied by the nerve as demonstrated at the operating table. For the sake of comparison they are classified in a manner similar to those demonstrated in the anatomical laboratory (Table I). The percentages are calculated on the basis of the possible total of 140 nerves.

Group I. Nine nerves (7 per cent) were demonstrated partially penetrating the gland. To release the recurrent nerve from this its most vulnerable position meticulous and deliberate dissection is required to avoid injury.

Group II. Forty-five nerves (32 per cent) 24 on the right and 21 on the left side were identified coursing through the adherent zone in a very intimate position to the gland necessitating careful blunt dissection for the intact preservation of the nerve.

Fig. 3. Variations in the course of the recurrent laryngeal nerve. a, In tracheo-esophageal fistula; b, through adherent zone; c, partially penetrating gland; d, division of nerve.

Fig. 4. Anteroposterior and cross section views showing partial penetration of the thyroid gland by the recurrent laryngeal nerve. Anteroposterior view and cross section demonstrating left nerve through the gland (after Gormley)

Group III Eighteen nerves were identified in the tracheo-oesophageal sulcus. Sixty-eight nerves were not identified at operation. Presumably they were safely concealed deep in the tracheo-oesophageal sulcus. When the thyroid was found deeply molded in the groove between the trachea and oesophagus, presenting either a retrotracheal or retrolaryngeal prolongation it was necessary to expose the course of the nerve in the sulcus to assure its protection. Fowler and Hanson

found 5 glands in 200 (2½ per cent) extending retrotracheally. In our operative series 4 glands (5.7 per cent) presented either retrotracheal or retrolaryngeal prolongations.

RELATIONS OF THE RECURRENT NERVE TO THE TRACHEA AND INFERIOR THYROID ARTERY

An observation made in the anatomical laboratory which has a practical surgical application concerns the relationship of the recurrent nerve to the lateral surface of the trachea. On the left side the nerve ascends in a vertical plane and is intimately applied to the trachea along its entire course in the neck. On the right side at the base of the neck, the nerve is frequently separated from the trachea to the average extent of about 1 centimeter, gradually approximating the trachea in its upward ascent and becoming closely apposed to the latter upon reaching the adherent zone. At the level of the lower pole the right nerve is often found thus separated from the trachea and in addition, usually travels in

TABLE I—CLASSIFICATION OF VARIOUS POSITIONS OF THE RECURRENT LARYNGEAL NERVES (ANATOMICAL DISSECTIONS OF BOTH NERVES IN 70 CADAVERS)

	Right	Left	Total Per cent
1 Partially penetrating gland	9	5	10
2 Through adherent zone	19	16	25
3 In tracheo-oesophageal sulcus	42	49	65
	70	70	100

TABLE II—CLASSIFICATION OF VARIOUS POSITIONS OF THE RECURRENT LARYNGEAL NERVES (SURGICAL OBSERVATIONS IN 70 TOTAL THYROIDECTOMIES)

	Right	Left	Total Per cent
1 Partially penetrating gland	5	4	7
2 Through adherent zone	23	20	31
a. Branching before entering larynx	1	1	1
3 In tracheo-oesophageal sulcus	8	10	13
4 Unidentified*	33	35	48
	70	70	100

* Presumably these nerves coursed beyond reach deeply in the tracheo-oesophageal sulcus.

Fig. 5. Recurrent nerve partially penetrating gland.

Fig. 6. Anteroposterior and cross section views demonstrating the recurrent laryngeal nerves coursing in the tracheo-esophageal sulcus deep to the gland.

Fig. 7. Variations in the relationship between the nerve and inferior thyroid artery. a, Right side: 1, nerve anterior to artery; 2, nerve posterior to artery; 3, nerve passing between terminal branches. b, Left side: 1, nerve anterior to artery; 2, nerve posterior to artery; 3, nerve passing between terminal branches.

a more anterior plane than its fellow opposite. This vulnerable combination of anatomical relationships has been often observed at operation. If not recognized the nerve may easily be caught in a snap or accidentally cut.

The cartilaginous prominence of the inferior thyrocartoid articulation affords an especially valuable surgical landmark for identifying the location of the recurrent laryngeal nerve as it enters the cavity of the larynx. For each of the 140 nerves dissected was seen to pass posteriorly to this articulation. Ziegelman, in a dissection of 42 recurrent nerves, also observed that all of the nerves presented a similar relationship to the inferior cornua of the thyroid cartilage on both sides. It should be again emphasized however that the nerve may arch anteriorly traversing the adherent zone

or partially penetrating the gland before dipping beneath the cornu (Figs 3b, 3c, 4a and 5). Fortunately in the majority of instances (65 per cent) the nerve ascends vertically in the tracheo-esophageal groove on both sides, beyond harm's reach.

Twice the nerve was demonstrated branching into two terminal twigs at about the level of the lower pole. The anterior branch coursed through the adherent zone and ultimately joining its posterior terminal companion beneath the inferior thyrocartoid joint (Fig. 3d). One such reasonably sizeable anterior branch was accidentally cut at operation on the left side after first identifying the posterior twig which was thought to be the main stem of the nerve with a resultant partial temporary paralysis of the corresponding vocal cord.

Fig 8. Histological resemblance between recurrent laryngeal nerve and an ordinary peripheral nerve. a, Recurrent laryngeal nerve. High power showing nerve fibers with 1 axis cylinders, 2 myelin sheath, and 3 neurolemma. X925. b Subscapular nerve. High power showing nerve fibers with 1 axis cylinders 2 myelin sheath and, 3 neurolemma. X925

In a previous publication (4) the results of 22 neck dissections disclosed, in a comparison of both sides a marked discrepancy in the relationship existing between the recurrent nerve and inferior thyroid artery. It was pointed out that the nerve was much more often anterior to the artery on the right side than on the left side. In this present series a reasonable but not so pronounced difference between the two sides was observed in the relationships of these structures (Figs 7a and 7b)

	Left	Per Cent	Right	Per Cent
Posterior to artery	44	63	31	44
Anterior to artery	17	24	38	40
Between terminal branches	9	13	11	16
	70		70	

It is obvious from this table that the nerve may frequently be anterior to the artery on either side and the surgeon must be constantly on the alert to recognize such variations when invading the danger zone in the final steps of total ablation of the thyroid gland

EMBRYOLOGY AND ANOMALIES OF THE RECURRENT LARYNGEAL NERVE

Accidental injury to the nerve is most likely to occur when its position is anomalous.

Fortunately however anomalies of the recurrent laryngeal nerve are rare. The only type which has been encountered in the literature is an anomalous course of the right recurrent nerve, which seems to occur in about 1 of every 500 persons. It appears to be more frequent in negroes (1). In the cases described, the nerve becomes separated from the main trunk of the vagus at about the level of the cricothyroid articulation. It may then run on in the carotid sheath for as much as 5 centimeters before passing medialward to the tracheo-oesophageal sulcus, up which it runs to a normal distribution as the inferior laryngeal nerve (1, 3, 10, 13, 14). In some instances the nerve may not actually exist as such, being replaced by several smaller filaments (1, 13). This anomaly has regularly been observed in association with an abnormal aortic arch, the right subclavian artery, instead of coming from the innominate of that side, arising either as the last branch of the aortic arch or from the dorsal aorta itself. In those cases to the reports of which we have had access the subclavian artery passed behind the trachea and oesophagus to the right arm (1, 14).

Fig. 9. a, Recurrent laryngeal nerve. Low power showing two fasciculi, 1 perineurium, and, 2 endoneurium. X75
b Subscapular nerve. Low power showing five fasciculi, 1 perineurium, and, 2 endoneurium. X75

This association of anomalies is easily explained on an embryological basis. In Figure 1 (12) it will be seen that in the young embryo the inferior laryngeal nerves leave the vagus in the neck and pass medially and dorsally under the fifth aortic arch to the site of the larynx. In the normal course of events as the heart and the great vessels descend into the thorax the left nerve is dragged down by the ductus arteriosus, which eventually comes to lie in the vertical plane so that the nerve appears to hook around the aorta. The right nerve on the other hand is pulled down by the fourth arch which later becomes the subclavian artery. If the fourth aortic arch on the right side fails to develop and the subclavian artery of that side comes directly off the aorta, the right recurrent nerve has only the internal carotid artery above it. Thus in man is almost vertical in position and naturally does not pull the nerve down to any great extent so that the latter goes almost directly across the neck from vagus to larynx (Fig. 2).

One would expect that in persons with right sided aortas, any anomaly of the recurrent nerve would be on the left side. To our knowledge no such case has appeared in the literature, but the findings in one that was seen in the Harvard anatomical laboratory last winter were very kindly furnished by Dr. Weatherford of that school. There was a right sided aorta, from the dorsal portion of which the left subclavian artery sprang to pass

behind the trachea and oesophagus on its way to the left arm. On the right, the recurrent nerve looped around the aorta as would be expected. On the left however the nerve left the vagus at the level of the subclavian artery, looped around a strand of fibrous tissue in front of the vessel and ascended the neck in the tracheo-oesophageal sulcus as usual. To explain this anomaly we must assume that the fibrous tissue about which the nerve hooked represents the sclerosed remnant of either the fourth or fifth left aortic arch.

VULNERABILITY OF THE RECURRENT LARYNGEAL NERVE

Crisle contends that the slightest direct or even indirect pressure on the nerve will interfere with its conduction and immediately change the voice. We have not observed this extreme sensitivity of the nerve to such slight trauma. While the possible inclusion of the recurrent nerve in a ligature is viewed with considerable fear its vulnerability because of certain characteristics in its conductivity (7) is not as great as has been supposed. This was our experience in 43 patients in whom one or both nerves were demonstrated at operation and subjected to manipulative insult such as would ordinarily attend this type of a dissection. There were 8 temporary vocal cord paralyses. Knowing that in some instances paresis followed the inadvertent pinching of the nerves, it seems probable that trauma of this character was responsible for the pareses.

in these instances. There were three permanent unilateral cord paralyses. One of these was proved at post mortem to result from ligation, another resulted from accidental section of the nerve. In no instance did permanent bilateral vocal cord paralysis develop.

The foregoing clinical observations are in accord with the animal experimental findings of Judd, New, and Mann, who demonstrated that while stretching will not result in any impairment of nerve function pinching will cause temporary paralysis of the corresponding cord, and that permanent cord paralysis will follow ligation or severance of the nerve.

The recurrent laryngeal nerve has been designated as being soft and naked, in contrast with a peripheral nerve (7). Histologically, there does not appear to be a valid basis for this differentiation (Figs 8a, 8b, 9a, and 9b). Both the recurrents and the peripheral nerves are furnished with a myelin sheath and a neurolemma (sheath of Schwann). A naked nerve is considered to be one devoid of these coverings. Furthermore, the perineurium or connective tissue element in the recurrent laryngeal nerve is essentially as abundant as in the average peripheral nerve, hence its firmness and tensile strength should be comparable to those of a peripheral nerve.

THE IMPORTANCE OF LARYNGOSCOPIC EXAMINATION IN THE COURSE OF OPERATION

Laryngoscopic examination preceding each operation should be a routine procedure in the management of all thyroid surgery, in order to assure pre-operative normality of the vocal cords and to enable one to ascertain more accurately the postoperative incidence of recurrent nerve damage. Injury to both recurrent laryngeal nerves is a calamitous, but fortunately an uncommon complication of subtotal resection of the diseased thyroid gland. There is greater likelihood however, of such a tragic accident developing in the process of totally extirpating the gland, for, whereas in the customary subtotal thyroidectomy the danger zone of the recurrent nerves and the parathyroid glandules is not particularly disturbed, in total thyroidectomy this zone is deliberately invaded (2). Thus, in the

latter operation both nerves are exposed to the greatest possible harm, and the danger of bilateral nerve injury must be always regarded as imminent. As a precaution against the development of such a complication, a direct laryngoscopic examination of the vocal cords is made routinely after the removal of one lobe (9). This applies to cases in which operation has been done under local, as well as general anesthesia, for on occasion the voice may be apparently normal even in the presence of one sided nerve injury. The quality of the spoken voice, therefore, is not a reliable guide to the integrity of the recurrent nerve on the corresponding side operated upon. Such false reliance on the changes in the character of the voice may lead to serious consequences. In the face of vocal cord paralysis after extirpation of one lobe, operation is ended to avoid the possibility of bilateral nerve injury. In two patients this procedure was followed with subsequent return of function of the injured recurrent nerve, and successful removal of all remaining thyroid tissue at a second operation.

Recently, at the suggestion of Dr. L. M. Freedman, we have desensitized the throats of patients operated upon under local anesthesia by applying cocaine immediately preceding operation in order to alleviate the discomfort of direct laryngoscopic examination during operation.

SUMMARY

1. Attention is called to the increased danger of injury to the recurrent laryngeal nerve in total ablation of the thyroid gland over that present in partial thyroidectomy.

2. The recognized type of gross anomaly in the course of the nerve is described and an embryological explanation for it is offered.

3. A report of the dissections of 140 recurrent nerves in 70 cadavers is presented. The nerves are classified into three groups as they are found in the tracheo-oesophageal sulcus traversing the adherent zone or partially penetrating the thyroid gland itself. The incidence of the latter two positions is found to be sufficiently great to demand the concern of the surgeon constantly. Operative experience confirms these observations.

4 The importance of the inferior thyro-cricoid articulation as a guide to the location of the recurrent laryngeal nerve is strongly emphasized

5 Although the nerve is found to be anterior to the inferior thyroid artery more often on the right than on the left the disproportion is not extremely marked and this position of the nerve should be watched for on both sides of the neck

6 Clinical and histological evidence is presented to show that the recurrent laryngeal nerve closely resembles an ordinary peripheral nerve and that its vulnerability to trauma is not as great as previously supposed. It is felt that an accurate knowledge of the variable positions of the nerves is the essential factor in the prevention of bilateral injury to the nerve

7 The quality of the spoken voice cannot be relied upon to denote the presence of unilateral nerve damage. The necessity therefore for direct laryngoscopic examination after ablating one lobe of the thyroid as a prevention against bilateral vocal cord paralysis is again emphasized

I desire to express my appreciation to Dr. Charles G. Mirer, surgeon in chief of the Beth Israel Hospital, for his encouragement throughout this work.

I am indebted to Dr. Monroe J. Schlesinger, pathologist of the Beth Israel Hospital, for the preparation of histological material.

ALTERATIONS IN LIVER GLYCOGEN FOLLOWING THYROID, IODINE, AND GLUCOSE FEEDINGS

W D FRAZIER, M.D., AND H. FRIEMAN A.B., PHILADELPHIA
From the Laboratory of Research Surgery University of Pennsylvania

OF the numerous conditions in clinical practice in which a serious depletion of the liver glycogen may play an important part, none is more frequently encountered than is hyperthyroidism. Although the exact relation of thyroid function to the regulation of carbohydrate metabolism is as yet a moot point, there is sufficient available evidence published by different investigators—Cramer and Krause, Boesl, Zimmerman, and Knittel—to state that the feeding of desiccated thyroid extract to the cat, rat, mouse, guinea pig or rabbit results in a reduction of the liver glycogen.

While certain of these investigations may be criticized because of failure more adequately to control the conditions surrounding the experiments, the data may be accepted as a whole as there is no essential disagreement between them.

We were primarily interested in whether or not the liver glycogen would be increased in the presence of experimental hyperthyroidism by the addition of glucose to the normal diet. During these investigations we have also had the opportunity to obtain additional evidence on the effect of the iodides on the circulating thyroxin.

METHOD

The animals used in these experiments were guinea pigs from one stock. They weighed from 400 to 600 grams. Purina rabbit pellets, which contain approximately 16.5 per cent of protein, 4 per cent of fat, 52.8 per cent of nitrogen free extract and 7.8 per cent of fiber were used for feeding. The pellets were pulverized and remolded into squares containing approximately 16 grams.

When thyroid extract, potassium iodide or glucose was added to the diet, it was mixed with the pellets during the process of pulverizing.

The pigs were weighed daily at the same time before feeding. Special feedings were as a rule not begun until each group had been

observed carefully for at least 1 week and the animals had shown a normal weight increase during this period. In the special feeding experiments, only data from those animals which ate all the food given them are included.

After a variable period of feeding, the pig was stunned by a cranial blow, the abdomen immediately opened, a small piece of liver rapidly removed and dropped into 5 cubic centimeters of a 40 per cent solution of sodium hydroxide, which had previously been placed in a 50 cubic centimeter centrifuge tube and weighed. The tube with the sodium hydroxide and piece of liver was immediately reweighed to obtain the weight of the liver sample.

The time from stunning the pig until the liver sample was placed in the sodium hydroxide never exceeded one minute and as a rule was less than 30 seconds. Duplicate samples were run in each experiment.

The extraction of glycogen from the liver was carried out by Sahyun's modification of the Pflueger method. After extraction of the glycogen and its conversion into glucose, the latter was determined by the Somogyi modification of the Shaffer-Hartman method.

RESULTS

Control guinea pigs. The pigs used in this group were fed the standard diet for 6 to 19 days. They gained in weight and were in excellent condition at the time they were killed. The last feeding was given 24 hours before death although the animals ate food over a part of this period. The data from the animals in this group are given in Table I. Each pig gained in weight. The liver glycogen varied from 3.2 to 8.6 per cent.

Thyroid fed guinea pigs. The animals in this group received in addition to the standard diet 0.5 gram of desiccated thyroid extract¹ daily, after a trial period on the standard diet during which they gained in weight. The

¹Park, Davis & Co.

4. The importance of the inferior thyro-cricoid articulation as a guide to the location of the recurrent laryngeal nerve is strongly emphasized.

5. Although the nerve is found to be anterior to the inferior thyroid artery more often on the right than on the left the disproportion is not extremely marked and this position of the nerve should be watched for on both sides of the neck.

6. Clinical and histological evidence is presented to show that the recurrent laryngeal nerve closely resembles an ordinary peripheral nerve and that its vulnerability to trauma is not as great as previously supposed. It is felt that an accurate knowledge of the variable positions of the nerves is the essential factor in the prevention of bilateral injury to the nerve.

7. The quality of the spoken voice cannot be relied upon to denote the presence of unilateral nerve damage. The necessity, therefore, for direct laryngoscopic examination after ablating one lobe of the thyroid as a prevention against bilateral vocal cord paralysis is again emphasized.

I desire to express my appreciation to Dr. Charles G. Mixer, surgeon in chief of the Beth Israel Hospital, for his encouragement throughout this work.

I am indebted to Dr. Monroe J. Schlesinger, pathologist to the Beth Israel Hospital, for the preparation of histological material.

we are reporting add additional evidence to Kunde's data and furthermore show that as long as the thyroid hormone gains access to the blood stream the liver stores of glycogen continue to be markedly reduced. The observations of Marine and of Frazier and Mosser that the beneficial effect of iodine in hyperthyroidism is the result of its effect on the thyroid gland itself would seem to be strengthened.

Of considerable importance are the data relating to the inability to increase the glycogen store of the liver during marked hyperthyroidism. It would seem that the effort to do this is wellnigh worthless unless the hyperthyroidism can be controlled either with iodine or operation or both.

Operation for hyperthyroidism without question throws an additional load on glycogen stores which are reduced in severely ill patients even under the best of conditions. Therefore, the value of attempting to restore the liver glycogen by the judicious use of carbohydrates immediately after operation should be emphasized. The intravenous method would at this time seem to offer the most rapid means of doing this in patients very ill after operation. In this regard the observations of Frazier and of North are extremely interesting.

CONCLUSIONS

1 The addition of thyroid extract to guinea pigs receiving a diet, which without the thyroid extract permits of a gain in weight, results in a depletion of the liver glycogen.

2 The addition of iodine to the diet of an animal receiving thyroid extract fails to prevent the depletion of the glycogen stores of the liver.

3 The addition of glucose to the standard diet of guinea pigs receiving thyroid extract fails to restore the liver glycogen.

4 The implications of these data with respect to the management of patients with hyperthyroidism have been pointed out.

STUDIES IN BONE SARCOMA

III AN EXPERIMENTAL AND PATHOLOGICAL STUDY OF THE RÔLE OF THE PERIOSTEUM IN THE FORMATION OF BONE IN VARIOUS PRIMARY BONE TUMORS

ALEXANDER BRUNSCHWIG M.D. F.A.C.S. CHICAGO
Department of Surgery and Division of Roentgenology University of Chicago

PAUL H. HARMON Ph.D. M.D. CHICAGO
Department of Surgery University of Chicago

IN the literature on primary tumors of bone there is considerable discussion concerning histogenesis, especially in regard to new bone formation. As again pointed out in a previous article (2) the group of primary bone neoplasms characterized by extensive atypical new bone formation in the primary growth and similar new bone formation in the soft tissue metastases affords conclusive evidence for the existence of the osteoblast or bone forming cell since these neoplasms represent a malignant degeneration of this cell. No other explanation can account for these tumors much less the explanation offered by the humoral school of osteogenesis which maintains that new bone formation in osteosarcomata is the result of a reprecipitation in the tumor of calcium absorbed from the osseous site of the tumor growth (5). Brunschwig and Harmon (3) showed that injection of calcium in several forms into growing transplantable soft parts sarcoma did not induce new tumor bone formation. In addition to new bone of tumor cell origin reactive bone or bone not formed by the activity of tumor cells, is often described in various types of primary bone sarcoma. In the literature there is little definite information concerning the source of this new non tumor bone, its relationship to tumor bone and to the tumor cells. Many years ago Ribbert pointed out that at the margins of extracortical portions of tumors of central origin there was an area of newly formed non tumor bone. This he stated was due to elevation of the periosteum by the adjacent expanding tumor mass (PL in Fig 12). These regions of newly formed non tumor bone are always sought for in roentgenograms when the diagnosis of bone tumor is considered. These areas have been called 'periosteal lipping' or "reactive tri-

angles. Ribbert made no attempt to correlate the cell type of the primary tumor and the extent of periosteal lipping nor did he attempt to determine a possible relationship between the elevated periosteum and new non-tumor bone formation within the tumor. The only additional observation made by this author was that tumor cells invading these reactive triangles destroy most of the newly formed non tumor bone leaving some fragments that are incorporated in the tumor mass as it expands in all directions.

The problem of the histogenesis of primary bone tumors would be greatly facilitated were it possible to cause malignant degeneration of a given type of cell in the bone of an experimental animal and compare the morphology of the resulting tumor with those observed in man. Such experiments not being technically possible at the present time it was decided to mimic them by placing fragments of a transplantable mesoblastic tumor in various locations in bone and observing the resulting neoplasm. These tumors correspond to the malignant degeneration in bone of mesoblastic cells which themselves, do not form bone.

EXPERIMENTAL

The transplantable neoplasm employed which originated in the abdominal wall is known as rat tumor 256 and was kindly furnished by Dr. Roscoe R. Hyde of the School of Hygiene of the Johns Hopkins University. Microscopically it is composed of round and spindle cells of various sizes the latter producing collagen. Numerous mitotic figures are present. The tumor grows at first by expansion and later infiltrates the surrounding tissues. Regional lymphatic and pulmonary metastases are produced in the later stages of growth. Successful transplantation is pos-

sible to almost all species of rats in over 75 per cent of the inoculations. Tubes of Rose now's beef broth and brain medium remained sterile for 3 weeks after inoculation with small fragments of the neoplasm. The tumor is not filterable even through Berkefeld V candles. Young adult white rats were used in the experiments. All operations were performed under aseptic conditions and ether anesthesia.

EXPERIMENT I

A. Small fragments of the sarcoma were placed beneath the periosteum of the shaft of the femur in three rats.

B. The knee joint was opened a sharp probe forced upward into the medullary cavity of the femur through its distal articular surface, and an elongated fragment of tumor pushed into the central portion of the femoral shaft in five rats.

C. A minute opening was made in the anterior crest of the tibia about 1 centimeter from the knee joint and a small fragment of tumor inserted into the medullary cavity in ten rats.

Four weeks after implantation, the extremities operated upon exhibited large tumor masses arising from the bone that seriously interfered with the function of the member. The animals were sacrificed at this time and the tumor masses were found to surround the bone into which transplantations had been made. The tumor adjacent to the shafts contained newly formed bone but roentgenograms were unsatisfactory in demonstrating its pattern because of the fine structure. Blocks of tumor including the shaft of the bone were fixed in formalin, decalcified, embedded in celloidin, sectioned and stained by hematoxylin and eosin and by phosphotungstic acid hematoxylin (Mallory).

Microscopic examination (Figs. 1 and 2) reveals that the tumor has grown through the cortex producing areas of absorption. Beyond the cortex, the accumulation of neoplastic cells elevated the periosteum for some distance. Finally the tumor has grown through and beyond the periosteum. In that portion of the tumor between elevated periosteum and cortex there are fine trabeculae of bone radiating at right angles to the surface of the

shaft. Between the elevated periosteum and cortex there are numerous fine connective tissue strands. It is in these strands near the shaft that the new bone has been laid down although on cursory examination it may seem that the bone was produced by metaplasia of the tumor cells (Fig. 4). Adjacent to the cortex these bony trabeculae appear quite mature, but as they are followed peripherally they become less mature in appearance and finally become continuous with bands of osteoid tissue. The latter in turn are continuous with the fine fibrous strands that extend to the periosteum. These strands appear to be fibers of Sharpey that have become elongated as the periosteum was elevated and thus maintained their connections between this membrane and the cortex.

The newly formed bone differs considerably in appearance in different zones in the same section. In places there are well defined bony trabeculae similar to those of normal cancellous bone. Elsewhere, the bony trabeculae are straight, long, and slender. There are also small areas in which recently precipitated calcareous granules are present about large rounded cells forming a lace like network in the intercellular spaces and presenting a picture not unlike the atypical tumor bone seen in malignant osteosarcomata in man (Fig. 4). Areas of cartilage are also present beneath the elevated periosteum in some of the sections (Fig. 5). Osteoid tissue when present is always between the most peripheral portion of the bony spicules and raised periosteum (Fig. 3).

In sections from some specimens, the periosteum is elevated over a considerable portion of the shaft, but there is not the extensive new bone formation throughout the subperiosteal zone as described above. Instead, there are scattered groups of radiating bony trabeculae and irregular islands of bone and cartilage. There is no apparent explanation for the differences in quantity of new bone in the different specimens although the extent of periosteal elevation was about the same in all cases.

It is stated above that the newly formed bone was of periosteal origin. This conclusion was based upon low power study of the

sections in which all the bone was found to be present only in the subperiosteal portions of the tumor. However from a microscopic study alone of the new bone under the higher powers especially those areas of atypical bone, it is impossible to state definitely that the tumor cells do not become incorporated into the bone since in many places they apparently can be seen in all stages of inclusion by bone as bone cells. Yet if actual metaplasia of tumor cells into bone cells did occur a true osteoblastic osteogenic sarcoma would have been formed. This however was not the case (see Experiment 1).

In addition to elevation and stimulation of the periosteum to new bone formation the tumor has also stimulated endosteal new bone formation. Short trabeculae of new bone are present radiating into the marrow cavity from the inner surface of the cortex. The cortex itself included within the tumor shows scattered areas of absorption a process like wise stimulated by growth of the neoplastic cells through it.

EXPERIMENT 2

Fragments of tumor including newly formed bone were obtained from the inoculated femur of some of the animals used in previous experiment and implanted beneath the skin into the liver the deep thigh muscles and dropped into the peritoneal cavity of other rats.

Two weeks later the animals were sacrificed. Sections of the tumors revealed that the neoplasm had grown profusely true to the original histological type. The fragments of bone were either completely absorbed or remained as small dead spicules in the centers of the tumor masses. Thus this bone behaved as does an ordinary bone homotransplant to subcutaneous tissue. This is additional evidence that all the bone formed in Experiment 1 was periosteal in origin and that the bone cells were not tumor cells, although histological study might have warranted such conclusions. Had the tumor cells become bone forming cells some of them would have continued growth as such in these transplants and have reproduced bone just as it is produced in ossifying metastases from certain osteogenic sarcomata (malignant osteoblastomata).

EXPERIMENT 3

A segment of bone 3 millimeters long was removed from the midshaft of the femur in each of 10 young adult rats, the contents of the medullary cavity removed and a small fragment of tumor pushed into the cavity. These segments were placed in the subcutaneous tissues of the flank in 10 other rats.

Three weeks later the tumors had become 2 to 4 centimeters in diameter. The rats were sacrificed and sections revealed that in 6 instances the segment of bone in the center of the tumor had died the neoplasm growing about it as a soft tissue sarcoma. In 4 instances the bone transplant also died but there had developed spicules of bone radiating from the surface of the dead segment similar to those seen in Experiment 1. The tumor had grown beyond and incorporated this new bone. Here again the new bone is formed from the periosteum which is elevated from the surface of the cortex by growing tumor. That in 6 instances no new bone formation is seen can probably be accounted for by the fact that revascularization of the osteoperiosteal transplant did not take place soon enough for survival of the periosteum.

EXPERIMENT 4

Periosteum was stripped from the femur from each of 5 young rats, wrapped about small fragments of tumor and placed in the subcutaneous tissues of other animals. Three weeks later gross and histological examination of the resulting tumors revealed no evidence of new bone or osteoid tissue.

OBSERVATIONS ON PRIMARY BONE TUMORS IN MAN

In the experiments described it was demonstrated that malignant mesoblastic cells growing from bone and not possessing osteoblastic properties, may elevate the periosteum and cause it to form bone. This bone is present in the form of spicules radiating at right angles from the surface of the cortex and is laid down in the tumor within fine connective tissue strands that extend from elevated periosteum through the mass of neoplastic cells to the surface of the cortex. All stages of osteogenesis are present depending

Fig 2 Photomicrograph of cross section of rat tibia into the medullary cavity of which a fragment of transplantable sarcoma had been implanted 4 weeks previously. A Elevated periosteum B New bone of perosteal origin in tumor C Tumor that has grown beyond elevated periosteum and contains no new bone D Cortex absorbed by growth of tumor through it $\times 12$

upon the area inspected. A short distance beneath the periosteum osteoid tissue and islands of cartilage may be present. Nearer the cortex the bone is more mature. Adjacent to the cortex the bone resembles normal cancellous bone.

The pattern of new bone formation in these experimental neoplasms is quite similar to that seen in certain types of bone sarcoma in man especially those forms of Ewing tumor in which there are fine strands radiating from the surface of the cortex. Soft tissue metastases from Ewing tumors do not produce bone thus showing that all the bone in the primary neoplasm is of non tumor origin.

Study of a large Ewing tumor of the upper half of the humerus removed from a 13 year old girl (Fig 7), shows precisely the same general morphology presented by the tumors produced in Experiment 1. The neoplasm was apparently of central origin, grew outward through the cortex elevating the periosteum for some distance from the shaft, stimulated osteogenesis and finally grew through and beyond the periosteum. A study of the gross specimen (Fig 7) shows the elevated periosteum with the new bone beneath it in the form of radiating trabeculae. Roentgenograms (Fig 8) show the uniform height of the trabeculae, indicating also the limits of the elevated periosteum within the tumor.

Microscopic examination shows compact masses of round tumor cells situated between

Fig. 3 Photomicrograph of a region in the extracortical portion of the neoplasm shown in Figure 2 showing *A* elevated periosteum *B* new bone *C* osteoid tissue in region between elevated periosteum and new bone $\times 75$

the straight trabeculae of non tumor bone that extend to the elevated periosteum. There are no areas in which the tumor cells vary in type to become spindle shaped and to appear to undergo osseous metaplasia. Some authors (Kolodny) however have incorrectly we believe stated that new bone in Ewing's tumors is both tumor bone and non tumor bone. All Ewing tumors do not exhibit the radiating spicules of bone that give the so called sun burst effect in roentgenograms. Some of them although of central origin are predominately osteolytic and when the periosteum is elevated by them they do not

Fig. 4 Photomicrograph of another region of extracortical portion of tumor shown in Figure 2 showing calcareous deposits about cells. This is an early stage of new bone formation in the tumor and from the histological examination alone it is not possible to state whether this is new bone of periosteal origin or whether it represents typical bone of tumor cell origin $\times 135$

stimulate its osteogenic properties to any appreciable extent. Roentgenologically such neoplasms are indistinguishable from fibrosarcomas of bone. The so called "onion" layers seen in roentgenograms of Ewing's and other neoplasms of bone is due we believe to alternating periods of rapid and slow growth. When the neoplasm grows rapidly no new bone may result or there may be a few radiating strands. When there is a period of relatively slow growth, the periosteum has an opportunity to form a layer of

bone analogous to an involucrum in osteo myelitis

In those osteogenic sarcomata in which the tumor cells themselves have osteoblastic properties as shown by their ossifying metastases to soft tissues the greater part of the newly formed bone in the primary growth is of tumor cell origin. Yet periosteal elevation may also be an important factor in new bone formation in the primary tumor as in the following case. A densely ossifying osteogenic sarcoma in the upper end of the tibia produced ossifying metastases in the inguinal lymph nodes and lungs. There is extensive new tumor bone formation throughout the intramed-

Fig 8 Roentgenogram of specimen of Ewing tumor primary in the humerus (specimen shown in Fig 7) showing radiating trabeculae of periosteal new bone. The rather uniform height of the radiating trabeculae indicates the level of the elevated periosteum. The peripheral portion of the tumor does not contain new bone because it has grown through and beyond the periosteum *PL*. Periosteal lifting new bone formed by elevation and stimulation of periosteum by adjacent expanding tumor mass.

ullary and extracortical portions of the tumor as shown in Figure 9 which is a roentgenogram of a sagittal slice of it. Figure 10 is a microscopic section of the slice. It shows the periosteum elevated posteriorly over the tumor by the expansile growth of the extracortical portion. Much new bone formation of periosteal origin is also present in the tumor. Study of the deepest regions of the extracortical portion of the neoplasm shows bony trabeculae, extending from the cortical surface that are obviously of periosteal origin, having been laid down as this membrane was being elevated by the expansile growth of the tumor mass. In these deeper regions the periosteal bone is being absorbed by tumor in the same manner as is the normal bone of the shaft included within the tumor.

Fig. 9. Roentgenogram of slice of osteogenic sarcoma in upper end of tibia, section of which is reproduced in following illustration. Note new bone formation in extracortical and intramedullary portions of tumor. The new bone in the extracortical portion is both of periosteal and tumor cell origin.

Fig. 10. Photograph of sagittal section 25 micra in thickness from osteogenic sarcoma in upper portion of tibia. There were also ossifying metastases in the inguinal lymph nodes and lungs *P* and *P*. Periosteum elevated posteriorly by expansile growth of tumor. *S* Region from which higher power photomicrograph was made (see Fig. 11) *M* and *M* limits of intramedullary portion of tumor \times .

On microscopic examination of limited areas of neoplasms such as just described mature bone of tumor cell origin may sometimes not be distinguished from non-tumorous mature bone (Phemister 7). Conversely as shown by the experimental tumors, there may be areas of new bone of periosteal origin that are very atypical (Fig. 4) and that resemble atypical bone of tumor cell origin. But where large sections are made through the entire neoplasm, the general topography of the newly formed bone in relation to periosteum and tumor cells is of considerable assistance in making a more accurate interpretation of the histogenesis of this bone.

Peripheral or periosteal osteogenic sarcomata arise from malignant degeneration of osteogenic cells (osteoblasts) in the periosteum or peripheral portion of the cortex. Figure 13 is a roentgenogram of a sagittal section

through the lower third of a femur bearing such a tumor. The neoplasm apparently arising in the posterior surface of the bone did not extend inwardly, the marrow cavity is free from tumor. Instead it had literally wrapped itself about the lower portion of the shaft and infiltrated adjacent muscles and fascia. Microscopic examination shows it to be composed principally of mature bone and large islands of hyaline cartilage some of which are undergoing ossification. This specimen illustrates how a peripheral osteogenic sarcoma involving periosteum at its point of origin may grow about other portions of the shaft on top of the periosteum. Thus the new bone within it, although in this case of mature appearance is entirely of tumor cell origin since the periosteum was not elevated. Figure 14 is a section from region *S* of Figure 13 showing the cortex with its periosteum

Fig. 11 Photomicrograph of peripheral area of extra-cortical portion of osteogenic sarcoma in upper end of tibia, taken in region indicated in Figure 10. *P*, Periosteum that has been elevated by expansile growth of tumor *PB* Periosteal new bone formation overlying peripheral margin of tumor *TB* Atypical bone of tumor cell origin situated within masses of neoplastic cells *PB* Trabeculae of periosteal bone that were formed as periosteum was being elevated by expansile growth of tumor. in place and ossified tumor *on top* of the periosteum

Chondrosarcomata of bone are the result of malignant degeneration of chondroblasts. Areas of new bone of tumor cell origin and calcified tumor cartilage are irregularly distributed within them. These represent maturation of certain portions of the tumor (6). When arising centrally these neoplasms may finally perforate the cortex and form large extracortical masses. Figure 15 is a roentgenogram of a slice of the upper portion of a tibia bearing a large chondrosarcoma. Irregular scattered masses of ossification and calcification are seen. In the inferior portion of the extra-cortical mass fine strands of bone radiating from the cortex are present. Gross and microscopic study showed that the periosteum was reflected over the tumor mass, having been elevated from the surface of the cortex. These fine radiating strands are composed of non-tumor bone having been laid down within and about the tumor by the periosteum as it was elevated and stimulated by the expansile growth of the tumor.

Fibrosarcomata of bone are osteolytic. When arising centrally they first destroy the

cortex and then by expansile growth elevate and later disintegrate the periosteum. Over such tumors the undestroyed elevated periosteum exhibits little or no osteogenic activity. If a few new bony trabeculae are laid down they are immediately attacked by eroding tumor cells and osteoclasts and are destroyed. Figure 16 is a microscopic section from the periphery of a fibrosarcoma arising in the upper portion of the tibia showing the beginning destruction of small bony trabeculae that were formed by the overlying elevated periosteum.

An interesting phase of the question is the factor or factors that govern the osteogenic activities of the periosteum when it is elevated by these neoplasms of various cell types. As was pointed out some of the neoplasms composed of malignant osteoblasts and some Ewing's sarcomata stimulate a high degree of periosteal new bone formation *within* them. Chondrosarcomata cause only a very limited amount of such new bone formation. Fibrosarcomata certain osteogenic sarcomata and some Ewing's sarcomata although elevating the periosteum extensively may stimulate very little or no new periosteal bone formation.

Fig. 1. Roentgenogram of slice of periosteal osteogenic sarcoma (implanted on oblique tibia) in rat. Ver lower portion of femur. *O* Area of periosteum or superficial region of cortex from which the neoplasm arose. *C* Large mass of cartilage with resorbing ossifications. *U* Medullary cavity free from neoplasm. *T* Portion of neoplasm that grew about shaft on top of periosteum and cortex. *P* Narrow cleavage zone between tumor and surface of cortex denoting the presence of periosteum that has not been elevated from cortex. *S* Area from which the microscopic section shown in Figure 14 was taken.

Not enough information is at hand to explain this relationship between these tumor cells and the osteoblastic activity of the periosteum and endosteum. Such new bone formation might be excited by mechanical disturbance as from elevation and stretching of periosteum by the expanding tumor. It might also be excited biochemically by substances of tumor cell origin. That the periosteum tends naturally to form new bone when simply elevated is shown by the fact that at margins of the extracortical portion of these tumors periosteal lifting is always present to some extent.

In conclusion, mention may be made of the recent work of Berg in which a filterable tumor producing agent was injected into the medullary cavities of the tibia in chickens. In the resulting neoplasms there were fine closely applied trabeculae of bone radiating

Fig. 4. Photomicrograph from area *S* in previous illustration. *T* Bone forming sarcoma. X435.

from the surface of the cortex. A study of the illustrations accompanying this report shows that the bone is entirely of periosteal origin due to the elevation of this membrane by the expanding tumor as in the experiments described above and not due to osteoblastic properties of the tumor cells as inferred by this author.

SUMMARY AND CONCLUSIONS

1. A transplantable rat sarcoma originating in the abdominal wall the cells of which do not exhibit osteogenic properties was inoculated into the medullary cavity (and beneath the periosteum) of long bones. The neoplasm grew through and considerably beyond the cortex, elevated the periosteum and caused it to lay down new bone in the form of radiating trabeculae within the tumor.

2. Additional experimental evidence is also presented to show that all of the new bone in these tumors was periosteal in origin and not due to osteoblastic properties acquired by the tumor cells as a result of implantation within bone.

3. In osteogenic sarcomata (malignant osteoblastomata) in man elevation of the periosteum by the growing neoplasm may be an important contributing factor to new bone formation even though the tumor cells themselves also exhibit osteogenic properties.

Fig 15 Roentgenogram of slice of chondrosarcoma arising in the upper portion of the tibia. *TB*, Scattered areas of tumor bone and calcification are present in the extracortical mass. *PB* Fine radiating strands of periosteal bone

4 In Ewing's sarcoma metastases to soft tissues do not ossify yet within the primary growth there may be strands of bone radiating from the cortex. All of this new bone is of periosteal origin being laid down as the tumor elevates this membrane by expansile growth. The mode of new bone formation in this type of neoplasm is quite analogous to that in the experimental tumors described. The onion layers of new bone in Ewing tumors are also of periosteal origin.

5 In the extracortical portions of chondrosarcoma fine spicules of bone radiating from the cortex may be present. These are of periosteal origin in contrast to the irregular areas of calcification and ossification that are scattered within the neoplasm and that are of tumor cell origin.

6 When periosteum is elevated over the osteolytic fibrosarcoma of bone its osteo-

genic properties are little if at all stimulated.

7 There is no apparent explanation for the variation in osteogenic activity on the part of the elevated periosteum which is seen in the several types of primary bone tumors which have been described unless this activity rests in the biochemical properties of the tumor cell.

LYCOPODIUM GRANULOMA¹

I. H. LRB, M.B. TORONTO, CANADA

From the Department of Pathology, Hospital for Sick Children, Toronto

By the term lycopodium granuloma is meant a granulomatous lesion developing in certain tissues after operation as the result of the introduction of lycopodium spores into the field of operation. Of recent years in many hospital operating rooms it has been the custom to use a dusting powder for gloves composed of a mixture of lycopodium spores and talcum powder; this is apparently an excellent preparation for the purpose. It is easily sterilized, keeps the gloves dry and serves as a lubricant so that they may easily be pulled over the hand.

Lycopodium powder consists merely of the spores of a species of club moss, *Lycopodium clavatum* which belongs to the fern family. While the plant is native to Europe, Asia, and America the spores for commercial purposes are collected chiefly in central Europe. The powder which has been called also vegetable sulphur is pale yellow, smooth, fine, very mobile, floating on water and not wetted by it, and burning with a quick flash when thrown into a flame. Talc is magnesium silicate which is rather an inert material. In powder form this has rather a soapy feel and is an excellent dusting powder and lubricant. The ease with which lycopodium spores gain entrance to the tissues during the course of an operation requires no explanation. In the cases here reported granulomatous lesions were found around lycopodium spores which had evidently been implanted in the tissues during previous surgical procedures.

The lesion is essentially a foreign body reaction to these spores; the spores themselves having been killed during the process of sterilization. It is composed of granulation tissue

arranged in the form of nodules about the foreign body. The older nodules bear a striking resemblance to tuberculosis, showing endothelial cells, multinucleated giant cells, varying degrees of fibrosis and lymphocytic infiltration with sometimes areas of necrosis or caseation. The spores may be found in the granulation tissue, the areas of necrosis or in giant cells. They are hollow spheroidal bodies measuring about 30 microns in diameter with scalloped or serrated margins and protruding from the surface are numerous spinous processes. When intact the outer surface presents a dimpled appearance not unlike that of a golf ball. On cross section they appear as a ring and contain a coarsely granular material. In haematoxylin and eosin sections they stain poorly; however with the Ziehl-Neelsen preparation they stain a brilliant red.

REPORT OF CASES

CASE 1: A R. male, aged 5 years, had suffered from chronic bronchitis and maxillary sinusitis for several years. He attended the out-patient department of the Hospital for Sick Children in 1932. In August of that year his antrum was irrigated repeatedly and on one occasion was injected with iodized poppy-seed oil. He returned about one year later with his symptoms persisting. In October, 1933 a radical antrum operation was performed and fragments of antral mucosa were sent to the laboratory for examination. The microscopic appearance of the lesion is shown in the accompanying photomicrographs. The general picture, as seen in Figure 1 is that of a conglomerate "tubercle" with fibrous and peripheral lymphocytic infiltration. In the centers of the tubercles can be seen endothelial cells, multinucleated giant cells, and, in one instance, a small oval, pale staining granular spore. Figure 2 shows another "tubercle" with central caseation and one of the spores stained acid fast.

Fig. 1 Case 1 Maxillary antral mucosa hematoxylin and eosin $\times 35$

Fig. 2 Case 1 Ziehl-Neelsen followed by hematoxylin and eosin $\times 105$

The tissue in this case was examined some 14 months following previous surgical treatment at which time it would appear that the spores were introduced.

CASE 2 B B male, aged 9 years, was admitted to hospital December 8 1931 and died April, 26 1932 of cirrhosis of the liver of about 8 months duration 3 months following an exploratory laparotomy at which operation the liver was palpated. The lycopodium lesions, which were confined to the surface of the liver were not noticed at the time the sections were first studied, and it was only during a review of our cases of cirrhosis of the liver some months later that the true nature of these superficial lesions was recognized. The microscopic picture bears a striking resemblance to that seen in Case 1 (Figures 3, 4, 5).

CASE 3 This patient developed symptoms of intestinal obstruction 2½ years following appendectomy. A second laparotomy was performed by Dr D E Robertson, to whom I am indebted for the clinical notes and the biopsy material and with whose kind permission this case is being reported. Old adhesions were found at the site of the previous operation. These were severed and the symptoms relieved. During the operation several small, whitish nodules were seen studding the peritoneum in the iliocecal region. One of these was removed for section. Its microscopic structure is shown in Figure 6. While the general appearance is similar to that in the 2 previous cases, the fibrous tissue is more dense, and caseation is more extensive. This may be accounted for by the longer interval of time (2½ years) which had elapsed between the two operations.

CASE 4 W K male was first admitted to hospital November 25 1931 at the age of 10 years, for appendectomy. At that time the appendix which contained a number of pinworms, showed no evidence of acute or chronic inflammation and the boy made an uneventful recovery his temperature falling to normal 48 hours after operation. He was readmitted February 21 1934 with typical signs and symptoms of intestinal obstruction of about 24 hours duration. The abdomen was opened and the

obstruction was found to have occurred as the result of adhesions around the site of the previous operation. About 12 inches of small bowel was gangrenous. This was resected. Scattered over the peritoneum in the neighborhood of the adhesions were numerous small whitish nodules. One of these was removed and its microscopic structure is shown in Figures 7 and 8. Following the second operation the patient made an uneventful recovery.

CASE 5 A boy D L, aged 7 years, died of a malignant endothelioma of the pleura. Because of pressure on the spinal cord resulting from invasion of the spinal canal by the tumor a laminectomy was performed. Five weeks later the boy died and examination of the tissues in the region of the operation revealed a granulomatous reaction with numerous foreign body giant cells, some tubercle formation and here and there the presence of lycopodium spores. In addition however to the spores there were also present small apicules of bone and what appeared to be the remains of suture material.

CASE 6 A S male, aged 12 years, died in the Hospital for Sick Children August 15 1933 of an abscess in the left frontal lobe. Two months before his death this abscess had been drained and a rubber drainage tube had been inserted. At autopsy the brain tissue immediately surrounding the tube bore little resemblance to cerebral cortex. There was proliferation of glia cells with some polymorphic infiltration. In addition there were quite numerous foreign body giant cells in which an occasional lycopodium spore could be found.

DIAGNOSIS

While as stated above these lesions bear a striking resemblance to tuberculosis, the essential feature in the diagnosis is the finding of the foreign body nucleus. To this end one must be familiar with the appearance of the spores. This, while quite characteristic as shown may readily go unrecognized on superficial examination as the spores stain

Fig. 3. Case 1. Lesion on surface of liver. hem. toxilin and eosin. $\times 30$

Fig. 4. Case 1. An unstained spore can be seen in the center of the area of caseation, hematoxylin and eosin. $\times 30$

Fig. 5. Case 2. Ziehl-Neelsen, hem. toxilin and eosin. $\times 300$

very poorly in routine hematoxylin and eosin sections. In doubtful cases the acid fast stain should establish the diagnosis. Because of the striking resemblance to tuberculosis, one must not be led astray by the presence of caseation as this may be fairly extensive (Fig. 6). On the other hand it should be pointed out that the mere finding of a few lycopodium spores in a given section does not necessarily mean that they are the cause of the lesion. Because of their peculiar reticulated surface they readily adhere to any tissue so it is quite conceivable that biopsy material might become contaminated by spores from the surgeon's gloves at the time of its removal. In this case they might be found around the periphery of the tissue. In order to incriminate the spores as the causative factor in a given lesion they must be found within the giant cells, or at least within the nodules of the lesion. The question as to whether or not the tissue under investigation has been the site of a previous operation should also be borne in mind. Another important factor is the locality of the lesion; for example, tuberculosis of the antrum would be extremely rare without evidence of clinical tuberculosis in other parts of the body.

LITERATURE

The literature on the subject of foreign bodies in general is rather extensive. The reaction in the surrounding tissues apparently varies with the nature of the tissue and with the size, shape and chemical composition of the bodies themselves. Under the title of "Nodular Lesions of Peritoneum" Haythorn recently reported a series of nearly 30 cases chiefly foreign body granulomata due to animal parasites, extravasated blood, gelatinous substances, oils and free fats, extruded stomach and intestinal contents and extraneous foreign bodies. Under the latter group he includes sutures, threads, bits of sponge and so on, but while his article is very comprehensive only four lines are devoted to this group in which no reference is made to lycopodium. The same appears to be true of all the other articles dealing with foreign body lesions with the exception of a recent article by Antopol. He reports 6 cases and refers to 2 others; his photomicrographs show lesions almost identical with those reproduced here. He also mentions that similar lesions may be produced by talc crystals. Thus far we have not encountered any such in human material.

Fig. 6 Photomicrograph in Case 3. Ziehl-Neelsen, hematoxylin and eosin X50

DIFFERENTIAL DIAGNOSIS

It is my purpose to draw attention to a type of lesion the significance of which in the past has no doubt frequently been unrecognized.

Lycopodium powder has been used in the past to produce foreign body granulomata in experimental animals. This being the case one need not be surprised if such lesions develop in the human body after their accidental introduction into the field of operation.

As the title might suggest that one is dealing with some sort of fungus disease, it should probably be emphasized here that the reaction is essentially a foreign body one the spores having been killed by sterilization previous to introduction into the tissues. That it is only a foreign body reaction however is another matter. The fact that the spores are acid fast, as are also tubercle bacilli and that the lesions produced by the spores are almost identical with tubercles even to the production of caseation leads me to believe that the chemical composition of the spores may be an important factor in determining the type of reaction. According to the United States Dispensary lycopodium spores contain "48.5 per cent of a neutral non-drying oil, very similar to almond oil. This oil contains 2 per cent of a fatty acid called lycopodic acid ($C_{18}H_{34}O_2$) 80 per cent of oleic acid, a minute quantity of a vegetable cholesterol similar to that obtained by Hesse from Calabar beans 8.2 per cent of glycerin and 3 per cent of arachidic, palmitic and stearic acids." It is no doubt this oily structure of the spores that causes them to burn with such a rapid and bright flash when thrown into a flame. That such a chemical composition should in

Fig. 7 left Case 4. Hematoxylin and eosin X90.

Fig. 8 Case 4. Three spores can be seen in the upper half of the field Ziehl-Neelsen hematoxylin and eosin X90.

fluence the type of reaction is more than probable. This view would seem to be supported by recent experimental work of Gardner and Cummings, working with silica and aluminum oxide. By intravenous injection into rabbits of fine particles of both these substances these investigators were able to produce a "typical hyaline nodular silicotic fibrosis of the liver by means of silica while the same sized particles of aluminum oxide were merely phagocytosed and produced no fibrosis. They conclude their article in the following words "These observations support the viewpoint that the injury produced by silica is specific and chemical rather than physical in character." The same I believe is true of lycopodium spores.

While lycopodium spores are obviously capable of producing lesions in the tissues such lesions are not to be regarded as necessarily injurious to the patient. Of the 6 cases here reported in 3 (i.e. Cases 2, 5, and 6) the course of the disease was probably in no way modified by the presence of lycopodium granulomata. The same, however can hardly be said of the 3 other cases. In Case 1 it is quite possible that the presence of the spores in the antral mucosa may have produced an aggravation of symptoms. When one recalls that the an

trum of a 5 year old child is, at best quite small anything that tends to produce a thickening of the mucosa might conceivably interfere with adequate drainage from the antrum. It is also conceivable that if spores were present in the wall of a discharging sinus, they might tend to cause persistence of symptoms. Cases 3 and 4 were similar in that both developed intestinal obstruction some 2 years after a previous appendectomy. That the adhesions which gave rise to the obstruction were caused in whole or in part by the lycopodium spores is difficult to determine. In Case 4 particularly the gross and microscopic appearance of the appendix and the post-operative course on the first admission would lead one to believe that had no spores been introduced there would have been no cause for adhesions to develop. Following the discovery of this case the use of lycopodium spores in dusting powder in this hospital was discontinued. In the last 2 cases reported the lesions found cannot be considered as due solely to the lycopodium spores. In Case 5 while spores were found in the granuloma at the site of operation other foreign bodies in the shape of chips of bone and suture material were also present. In Case 6 no spores could be seen in the field showing the greatest foreign body reaction their presence however within the tissues served to illustrate the ease with which they may be introduced into the held of operation.

Thus, while the presence of the spores in some instances may give rise to little or no

inconvenience to the patient they may lead to serious errors in diagnosis which may result in radical or unnecessary surgery. Antopol reports the case of a man who was admitted to hospital because of a persistent sinus and mass in the epididymis. He gave a history of operation for traumatic hydrocele 2 months previously. A clinical diagnosis of tuberculous hydrocele was made and an orchidectomy was performed. Microscopic examination proved the lesion to be a lycopodium granuloma.

SUMMARY

Six cases of lycopodium granuloma are here reported in which the spores were obviously introduced into the tissues during some previous operative procedures. In 4 of these cases the resulting lesions bore a striking resemblance to tuberculosis with which they might easily be confused.

Two of the patients developed intestinal obstruction from adhesions at the site of a previous operation and there is reason to believe that these were caused by the lycopodium spores. In the opinion of the author the use of lycopodium spores as a dusting powder in operating rooms should be discontinued.

FACTORS CAUSING DELAY IN OPERATIVE THERAPY OF CARCINOMA¹FREDERICK M. SMITH, M.D., NEW YORK
Fellow in Surgery, Presbyterian Hospital, New York

THIS study was based upon interviews with 95 patients. This is perhaps a small number from which to draw conclusions yet each case has been investigated personally by the author. All of the patients with 3 exceptions were admitted to the surgical wards of the Presbyterian Hospital in New York City. Of the 3 exceptions 1 was a private patient and the 2 remaining were seen in the Out Patient Department of the Vanderbilt Clinic. In all of the 95 cases a complete history and physical examination had been recorded upon the patient's chart. They were collected during a period of slightly more than 1½ years from October, 1929 to June 1931.

Practically every group of cancer patients studied shows a marked period of delay between the onset of symptoms and the time that they obtain proper treatment. It is the purpose of this study to determine what are the chief factors causing this delay. It is generally considered that cancer in its beginnings is a localized growth. Whether this be absolutely true or not makes no great difference. It is true that in many and possibly even in the majority of cases the growth remains localized for a brief period of time. This is one of the peculiarities of cancerous tissue that gives us some ray of hope, namely that we may possibly be able to eradicate the entire malignant tumor before any metastases have taken place. Without this hope there would be very little to look forward to in the treatment of cancer except the use of surgery or radiotherapy solely for palliative measures.

Summons and Daland in Boston analyzed the cases of malignancy of all kinds entering the Massachusetts General Hospital from 1917-1918 and 1921-1922 and found that there was an average of 12.5 months and 11.6 months respectively between the onset of symptoms and the appearance of the patient at the hospital. In the breast cases alone there was an average delay of 11.4 months and 12.4 months respectively which is

slightly greater than that found in the group of breast cases considered in this paper. J. M. Wainwright speaking on the reduction of cancer mortality states that the Pennsylvania Cancer Commission showed that 'in superficial cancers while the patient himself was aware of his condition for 1 year and 2 months the physician also had that knowledge for an average of 1 year. In deep-seated cancers the patient knew of the condition for 18 months and the physician knew of it for 13 months. Such delays are not limited to the State of Pennsylvania but have been and still are prevalent in every state in the country.

To return to the causes of delay, we may ask: What is to be considered as proper treatment? The answer is that proper surgical treatment in cases of malignant disease where surgery is applicable is *radical treatment*. In other words cancer is a deadly disease if untreated, if maltreated, or if given the correct type but inadequate amount of treatment. I mean by this that there are many patients that might have been saved had they been seen early and given radical treatment at the start.

The causes of delay in any group of cancer patients receiving what may be considered proper and adequate treatment are many but these may be classed under four main headings: ignorance or carelessness, fear, expense and lack of symptoms and disability. *Ignorance* may be blamed upon the patient himself upon his family, relatives or friends, and upon his local physician or the physicians seen in hospitals or clinics. *Fear* may be that of the patient toward the disease or toward the possibility of an operation. Fear of a member of the patient's family for the patient may in rare instances cause considerable delay. The *expense* of examination or of treatment (including operation) may keep a patient from consulting a doctor or from entering a hospital. The *lack of symptoms and of disability* is seen in a great many cases as a cause for

¹From the Surgical Pathological Laboratory of the College of Physicians and Surgeons, Columbia University, and the Surgical Department of the Presbyterian Hospital, New York. Submitted in partial fulfillment of the requirements for the degree of Master of Science to the Faculty of Medicine, Columbia University.

delay. Much of this delay is the result of lack of serious symptoms or lack of pain. How many times have we heard a patient when questioned concerning his duration of symptoms, remark, "It never bothered me so I didn't think it serious and paid no attention to it." More will be said about these causes of delay farther on.

The 95 cases were as follows: Carcinoma of the female breast 41 cases; carcinoma of the rectum 19 cases; carcinoma of the sigmoid colon or splenic flexure 10 cases; carcinoma of the stomach 8 cases; carcinoma of the cecum 6 cases; squamous cell epithelioma of the oral cavity 5 cases; and a miscellaneous group of 6 cases. This miscellaneous group consisted of one squamous cell epithelioma of the lateral neck region, one squamous cell epithelioma of the auricle, one carcinoma of the esophagus, one sarcoma of the gastrocnemius muscle, one melanoma of the eye and one angio-endothelioma of the thigh. Each one of these cases was considered malignant upon pathological examination except the first case which was obviously clinically a far advanced carcinoma of the breast.

The time lost since the onset of symptoms varied from 4 days in 1 case to 7 years in another. Where the time between the onset of symptoms and admission to this hospital was 2 weeks or less, it is fair to assume that such a short time cannot be considered as any real delay. There were only 4 such cases in this group. There were 2 other cases with a duration of symptoms of only 3 weeks and 2 more with a duration of only 4 weeks. The average duration of symptoms for the whole group was 11.6 months. This latter figure is identical with that found by Simmons and Daland for the year 1921-1922. If our figures are at all comparable, it shows that there has been no appreciable improvement in lessening the pre-operative duration of symptoms in cancer patients.

ANALYSIS OF GROUPS

A. Breast carcinoma. Of the 41 cases of carcinoma of the breast (all females) 25 had previously consulted physicians before coming to this clinic. Fourteen cases had consulted but one physician, 6 had consulted two physicians,

2 had consulted three physicians and 1 had consulted twelve physicians. Twenty three of this group of 25 patients had a definite palpable mass that had been noticed subjectively. 12 had some pain, 2 had consulted nurses in respect to the lump and 2 had sought treatment from a druggist without relief. Six had received definite bad advice or only local treatment from physicians outside. Eight patients were definitely delayed by carelessness or ignorance of the physicians examining them before they came here. There were 3 such cases in our own hospital. One was a patient examined and treated in the out patient clinic for dyspnea and in whom the lump was noted in the breast on physical examination. No diagnosis was recorded in the chart and the patient was never referred to the surgical department. She then disappeared for 15 months to return with a hopelessly inoperable carcinoma with local and distant metastases.

The second case was examined in the out patient clinic and the lump in her breast was considered benign. She was not seen by an attending surgeon on the day of her examination due to some error and there resulted an extra delay of 4½ months before she was finally admitted for operation. The third case may or may not have been treated earlier as she had noted a lump in her breast for only 5 months. It is interesting to note that 9 months previously she had had her heart and lungs examined in the emergency ward prior to taking a general anesthetic for treatment of an injury. One month later she was admitted to the hospital for an operation on her eye. On neither of these occasions was any note made by the examining physician in respect to her breasts.

Nineteen of the 41 patients may be partially or wholly to blame for their own delay either from ignorance or procrastination. There were 16 patients with breast cancer who had not consulted a physician before coming here. Each of these had a mass that she had noted herself. Twelve had had some pain referable to the breast or arm. In 15 the patient's own ignorance was largely the cause for her delaying consultation and treatment.

Nine patients of the entire 41 gave fear of the expense as a reason for their delays. 5 of

them gave this as their chief reason. Fifteen stated that fear of an operation was one of their reasons for delaying, 6 gave this as their chief reason. One patient, who had had a local removal elsewhere gave the fear of a second operation as her chief reason for delaying further treatment after she had had a local recurrence of the tumor. None of these breast cases had any real disability attributable to the breast condition. In all but 2 the symptoms noted by the patients were considered mild, and hence they put off seeking medical advice for many months. Only 2 patients stayed away for fear that they might have a cancer.

In these cases of breast cancer there was an average delay of 10 months between the onset of symptoms and the time the patient was admitted for operation (see Table I). There was an average delay of 3.2 months between the onset of symptoms and the time the patient first consulted her own doctor. The time lost between the first consultation with her doctor and the time she was admitted to this hospital for operation was 8.6 months on the average. The average delay from onset of symptoms when no outside doctor was consulted was somewhat less, namely, 7.3 months. This average delay is altogether too long if we hope to do any real good for the patients afflicted with breast carcinoma. It may be argued that some patients who consult a surgeon regarding a breast lump and have a radical operation for the same done within 1 or 2 weeks do not necessarily turn out to live the longest in the end. Some of these no doubt have extensive metastases in their axillary lymph glands or elsewhere at the time the lump is first noted in the breast. Of course if such be the case, the chances for a long cure following operation are small. However many of these patients do not have early metastases and again some patients who have had a known lump in the breast for a considerable period of time varying from many months to sometimes a year or longer still do not have axillary metastases at the time of operation. If this average delay could be cut down let us say 30 to 50 per cent there would unquestionably be a much larger number of 5 and 10 year arrests as a result.

TABLE I

Site	Number of cases	Average delay when no outside physician was consulted	Average delay between onset of symptoms and first consultation with a physician	Average delay between first consultation with a physician and operation	Average delay between first cancer symptoms and operation
Breast	45	7.3 mos	3.2 mos	8.7 mos	10.0 mos
Rectum	10	7.0 mos	4.8 mos	4.7 mos	9.1 mos
Sigmoid	10	7 days (1 case)	3.4 mos	3 mos	6.3 mos
Stomach	8	8.0 mos (1 case)	0 mos	6.6 mos	8 mos
Cervix	6	1.0 mos	3.1 mos	8.6 mos	3.3 mos
Oral cavity	5	12 mos (1 case)	8 mos	0 mos	10.7 mos
Miscellaneous	6	(Not included here as a group)			

This does not of course apply solely to breast cancers but is applicable to other types as well.

B. Rectal carcinoma. Of the 19 cases of carcinoma of the rectum 17 had consulted one or more outside doctors or clinics more than half of them had consulted two or more physicians. The patient's own ignorance in 15 cases was definitely responsible in part for the delay in obtaining proper operative therapy. Two gave fear of an operation as the chief reason for delaying and 2 more gave this as a contributing factor. Two likewise stated that fear of the expense was their chief reason for delay and 2 more gave this as a contributing factor. Nine patients (or more than half of the total number of the 17 who had consulted physicians) were treated symptomatically without having had a rectal (digital) examination made upon them. This is a deplorable state when such patients are complaining of symptoms referable in the greater majority of instances to the lower bowel. One such case occurred in our own out patient clinic. She had been examined and had been followed there for 10 months with increasing constipation as one of her complaints. The tumor in her rectum was only discovered at the end of this time when she was finally referred for surgical consultation and the first rectal examination was made and the tumor easily palpated. Another case in the hospital had

been proctoscoped and the mass in his rectum biopsied. Clinically at proctoscopic examination the mass had the typical picture of a carcinoma. The biopsy specimen was sent to the laboratory where it was diagnosed in correctly as a benign polyp. The patient was allowed to go home but his symptoms became more severe. He was finally readmitted 3 months later with a mass in his rectum that had increased to about three times its original size. Another biopsy specimen examined in the same laboratory was again diagnosed as benign polyp. A similar piece examined by another laboratory was diagnosed carcinoma. The patient was operated upon and an infiltrating carcinoma was found which had involved the adjacent lymph glands.

One patient was seen by three outside physicians none of whom had performed a rectal examination. The first of these was an insurance company physician who when asked by the patient what to do for his increasing constipation advised him to take mineral oil. He did no rectal examination although he was examining a patient who was taking out a life insurance policy. Another patient had been seen by five outside physicians all of whom she stated were specialists. One of these advised and performed a hemorrhoidectomy upon her without having done a proctoscopic examination. She was naturally not relieved of her condition but was caused an unnecessary delay of 8 months.

Space does not permit going into each case individually but these just cited may help to show what is happening in a relatively large percentage. Six of the 9 cases which had received no rectal digital examination had easily palpable tumors. The 3 others had tumors that were discovered without difficulty when proctoscoped in this hospital. Of the nine, 8 had symptoms that called for a rectal (digital) examination and the ninth had suggestive symptoms.

Lack of symptoms and lack of disability were of considerable importance in the delay of these rectal cases. In spite of this fact many of these patients had a number of symptoms such as pain constipation or diarrhea bleeding per rectum etc. they also had had a

definite change in their bowel habits which might have made them suspect something more than hemorrhoids or colitis. There was only one patient of the 19 who really had severe symptoms and was actually disabled by her condition. One other patient was prevented from having an operation by his private physician and his wife even after carcinoma of the rectum had been confirmed both by proctoscopic examination and biopsy in our clinic.

In these rectal cases there was an average delay of 9 1 months between the onset of the patient's symptoms and his admission to the hospital for operation. The time lost between the onset of symptoms and the first physician consulted averaged 4 8 months. That between his first consultation and his admission here for operation averaged 4 7 months. Only 2 patients came to the hospital who had seen no outside physicians. The duration of their symptoms was 2 months and 12 months, respectively.

C. Carcinoma of the sigmoid colon. Ten patients were studied with carcinoma of the sigmoid colon (in which is included 1 case of carcinoma of the splenic flexure). Nine of these consulted one or more outside physicians. Five had definitely received bad advice or treatment by these local physicians. In 8 of these cases the delay may be attributed in part to the patient's own ignorance either in not consulting a physician sooner or in not asking for a more complete examination with the assistance of X rays. One patient stated that fear of an operation was his chief reason for delay. Two others attributed the fear of an operation as one of their reasons for delay. In only one of this group was fear of the cost of treatment responsible for the patient's delay. More than half of all these patients had symptoms of constipation diarrhea, or bleeding per rectum which really called for X ray diagnosis by the adjunct of the barium enema. The X ray is not always conclusive as proved to be the case with one patient followed in our own hospital and clinic for 8 months before repeated X ray examinations finally showed an obstruction in the sigmoid colon. The one case not seen by any outside doctors came to the hospital with symptoms

of complete obstruction for 7 days. On repeated questioning he stated that he had never had any symptoms prior to this attack of pain and obstipation. Two patients had been observed at other hospitals in New York City, but when advised to have exploratory operations they refused because the diagnosis was not considered certain. It is only natural not to accept an exploratory operation on an uncertain diagnosis, but had the necessity for exploration been impressed more firmly on the patient, he might have accepted it sooner.

One case in this group with symptoms of 7 years duration had multiple polyposis of the colon and rectum and carcinoma of the sigmoid colon. It is hardly conceivable that operation for the polyposis at the onset would have cured him or prevented him from getting more polyps which might develop into carcinoma at a later date. For this reason this one case is omitted in calculating the statistics on delay in this group. The average duration of symptoms was 6.5 months. The average delay between onset and the first consultation with a physician was 3.4 months. The average delay between the first consultation and admission for operation at this hospital was 3.2 months. Early obstructive symptoms in these cases seem to account for the shorter delay as compared to the cases of rectal carcinoma. Lack of symptoms as well as only partial disability played a greater part in these delays than they did in either the breast or rectal cancers.

D. Carcinoma of the stomach. Although a small group this collection of 8 cases shows many pathetic instances in which early diagnosis and operation might have prolonged the patient's life very considerably and most of all would have relieved his symptoms for many months. There were 6 of these who put off seeing physicians early or who kept putting off an exploratory operation until very late. Only one patient attributed his delay in part to the fear of expense. None actually stated that the fear of the operation itself made him delay in seeking and obtaining adequate treatment.

Only one patient had not consulted an outside physician. His own family physician had

died, and he stated that he had no faith in any other. Consequently, he undertook to treat his increasing indigestion himself, as he did not think his condition at all serious. Of the 7 remaining, 5 were definitely given advice and treatment by outside physicians. Of the 2 others, both had been followed and treated in our own clinic or hospital. The first, a 60 year old woman, with digestive disturbances had been followed for 3½ years in the outpatient clinic. Her symptoms and signs were indefinite, the X-ray findings negative, and it was deemed inadvisable to operate with so little evidence pointing to a definite lesion. At the end of this time, a final X-ray showed "two ulcers of the stomach" and the patient was finally admitted for operation. Such a delay cannot be attributable to lack of keenness on the part of the physicians for she was seen frequently during this period and nothing positive could be found until very late. It is also unlikely that this patient's symptoms were due to a carcinoma for 3½ years. An ulcer was most probably the original lesion but unfortunately this could not be demonstrated at a time when operative therapy had much to offer.

The second patient, a 56 year old man, came to the hospital complaining of an inguinal hernia. At the time of his admission he had some vague gastric symptoms for which a gastro-intestinal X-ray examination was done which showed an "ulcer." He was then explored. A mass was felt in the pyloric end of his stomach which was thought by the operator to be "carcinoma or ulcer induration." One firm lymph gland was also felt near the pylorus. No biopsy was taken. A gastro-enterostomy, entero-enterostomy and appendectomy were then done. The patient finally returned 5 months later with symptoms of obstruction. At this time a second exploratory operation revealed metastatic nodules of tumor tissue scattered all over the peritoneum and a large mass in the stomach. No one can be dogmatic about the prognosis in individual cases, but it seems highly probable that this patient might have been greatly benefited by resection of the pyloric portion of the stomach at first operation had the operator not taken the chance of its being "ulcer induration."

Disregarding the one case of $3\frac{1}{2}$ years duration the average delay in these gastric cases was 8.1 months from onset of the symptoms to admission to the hospital. The average delay between onset of symptoms and the first consultation with a physician was 2.9 months. The delay between the first consultation and admission here for operation averaged 6.6 months. With very few exceptions, all these patients showed symptoms that were moderate or mild and none showed any real disability. Cancers of the stomach like cancers elsewhere show an insidious onset which explains the great delay in these patients seeking early treatment. Being so called internal cancer it is not easy to see how much improvement will take place in hastening these cases to get early diagnosis and adequate operative treatment.

E. Carcinoma of the cecum. Again this is a small group of cases (six) but each one delayed seeing a physician or refused what was considered adequate treatment when prescribed by a physician. Two had seen no physicians outside of this institution. Three were given definite bad advice or treatment by the physicians consulted. One was treated by her physician for pernicious anemia for 2 years. When she did not improve he advised having intestinal X-ray pictures taken on several occasions but his hands were tied by the patient who refused these on account of the expense. The fault in this case was not entirely his, as he presumably was considering the patient's finances. On the other hand, it unquestionably cost the patient more in the end, and had he insisted on the X-rays, he not only would have saved her money but would have been able to establish the diagnosis much earlier. One other patient in this group gave the fear of cost of treatment as her chief reason for delay. Another attributed the fear of an operation as a contributing reason for her delay.

The total average delay from onset of symptoms to admission to the hospital in these cases of carcinoma of the cecum was 13.3 months. The average delay from onset of symptoms to the first consultation with a private physician was 5.3 months. From this first consultation to admission for operation

in this hospital the average delay was 8.6 months. The 2 patients seeing no physicians prior to coming to the hospital each showed a duration of symptoms of 12 months. The delay in these cases is naturally longer than in those having carcinoma of the sigmoid. This is due largely to the different physiology of this portion of the bowel where fluid feces easily pass until the obstructing lesion becomes very marked. Other clinics have noted similar findings.

In only 3 of the 6 cases were symptoms shown that might be considered mild and their mildness acted as a contributing factor in their delay. None of the 6 showed any real disability.

F. Squamous-cell epithelioma of the oral cavity. There were 5 patients in this group. One had been in this hospital a year previously but her tongue at that time was giving her no trouble. She noticed nothing until after she had left the hospital and then did not consult a private physician or come back to have her tongue examined in the hospital until after nearly 1 year when she then had a definite epithelioma. This patient gives her sole reason for delay as being due to fear of the expense. Of the 4 remaining patients 2 had seen at least 2 physicians and dentists and 2 had seen at least 3. Two may blame their delay to a considerable extent to their own ignorance. One of these consulted a druggist and received treatment from him for several months before seeing a physician. All 4 were definitely given bad advice and treatment by the dentists and physicians they consulted. Of these 1 was treated with local applications for 7 or 8 months on a diagnosis of Vincent's angina, while the lesion which had first healed reappeared and became progressively worse under treatment. No biopsy had been taken. The second was treated with a small dose of radium in another hospital without a biopsy having been taken. He then went to a second hospital where a biopsy was taken and the patient referred to this institution. It might be argued that X-ray or radium was the proper treatment in this case. Even if this be conceded the dosage was most likely inadequate and in addition was not based on microscopic examination of a biopsy specimen. The

third case was seen by several dentists. He had three biopsies taken, the first two of which showed "benign papilloma" the third was lost. Finally after 10 months when an X ray picture showed an "infectious process in the mandible" the patient was referred to this hospital. The fourth case had a local removal 1 year previously by an oral surgeon, following which he was given either X ray or ultra violet light treatment. The lesion finally recurred 4 months later, but the patient put off going to see his dentist again for 3 more months. The latter then sent him to this hospital.

The average time lost in these cases between the onset of symptoms and admission to this hospital for operation was 10 2 months. All of the patients, with one exception, consulted a dentist or a physician within 2 months or less after the onset of the first symptom. The average delay between the first consultation with a dentist or a physician and admission to this institution for operation was exactly 9 months in the 4 cases that had sought any medical advice outside. Four of the 5 patients had little or no symptoms and no disability. This may account for some, but not all of their delay. The fifth patient had much pain and also disability. He sought treatment early and persistently. He, however, was the one who had had two "negative" biopsies and a third one that was lost and was only referred to us after 10 months of local treatment.

G Miscellaneous cases Since each case in this group is of a different type it is felt that a brief summary of the individual case would be better than trying to sum them up as a whole. It will thus be seen more clearly where the delay took place and to whom it may be attributed. The first case, a 33 year old woman, had a tumor in her neck for 2 years. She went for 18 months without consulting a physician. A friend had told her it was an "enlarged gland" and was of no significance. Finally when she consulted a physician he gave her "injections" for 3 months without relief. The tumor turned out to be a squamous cell epithelioma of the lateral neck region (the growth probably arising from a bran- chogenic rest).

The second case was that of a 37 year old woman with a tumor of her lower thigh of 3 years' duration. She had been treated by four private physicians without a diagnosis having been made, and without relief. She was afraid an operation might be necessary and for this reason stayed away from hospitals and clinics. At last a friend told her she might have a tumor and advised her to see another physician. This she did (at the end of 3 years) and was referred to this hospital. Her tumor turned out to be an angio- endothelioma.

The third case a 55 year old man, who had suffered for 7 months with difficulty in swallowing and a loss of over 60 pounds in weight, consulted no physicians outside of this hospital because he "did not think his condition amounted to anything" and because he was afraid of the expense. He turned out to have a carcinoma of the esophagus. There may be some doubt about early treatment being of benefit in this case, but it shows how a patient can neglect himself in spite of marked symptoms.

The fourth case, a 71 year old man, came to the hospital complaining of double vision, occasional pain and hugging of his right eye ball. The double vision had been present for 3 years. He saw a physician shortly after the onset who treated the condition with eye-drops without relief. Later he consulted an eye clinic where he was likewise treated with eye-drops. One physician at this clinic had suggested an operation but the patient states that "this never came to a final decision." He later saw three other physicians in turn and each of these treated his eye with drops. Following this he went to another hospital where a small dose of radium was given without relief. Finally at the end of 3 years, when his eye began to bulge, his daughter insisted on his coming to this hospital. His condition was due to a malignant melanoma that had broken through the sclera and had invaded the posterior part of the orbit, thus forcing the globe forward. Although the patient had paid little attention to his condition, even though it did not improve, a careful ophthalmoscopic examination early would probably have clinched the diagnosis and led to early adequate treat-

TABLE II—PERCENTAGE SURVIVAL RATE OF CANCERS WITH AND WITHOUT AXILLARY METASTASES AT OPERATION (AFTER STOUT)

	Three years postoperative		Five years postoperative	
	Alive	Apparently cancer-free	Alive	Apparently cancer-free
No metastases	63	47.5	54	46
All cases	45.9	3	3.8	3.3
Metastases	38.9	14.5	3	3

ment. The majority of the physicians seen by the patient were general practitioners who had merely made very superficial examinations of the eye and then proceeded to treat it symptomatically.

The fifth case a 33 year old woman consulted a physician 14 months previously for pain and cramps in the calf of her leg. He treated her for fallen arches, but the pain persisted though not severe. One year later she consulted another physician because the calf of the leg had become swollen. This physician incised the swelling in the belief that she had an abscess but found no pus. He took no biopsy and told the patient that he had found nothing suspicious. When she came to us a microscopic section showed a reticulum-cell sarcoma of the gastrocnemius muscle for which amputation was done.

The last case was that of a 56 year old man with a squamous cell epithelioma of the auricle which he had had for 2 years. He treated it himself for 6 months without success. He then consulted a physician who spent 12 months more treating it with salves and lotions but without success. At last the physician took the patient to a specialist who immediately referred him to this hospital.

SUMMARY

The lack of symptoms and the lack of disability play by far the greatest rôle in delaying cancer patients in seeking and obtaining what is considered proper and adequate treatment. Many of these patients have perfectly definite symptoms of their disease but it is a lack of severe symptoms or a lack of real disability that makes them not complain. This is the one characteristic of cancer particularly in its early stages, that seems to be

the bugbear of the medical profession in shortening the delay in these patients getting early treatment. As long as cancer rarely gives marked pain or other pronounced symptoms in an early stage it will remain particularly difficult to get patients to seek earlier consultation unless more impressive propaganda is distributed to the lay public. Two patients only in this group came to the hospital because of hearing or reading about cancer symptoms. Both were breast cases. One after attending a lecture on cancer came to the clinic for advice concerning a lump she had had in her breast for 30 months. The second with a lump in her breast of 3 years' duration had consulted twelve physicians, but had been reassured by each in turn that the lump was of no importance. She finally read several articles in the newspaper and then came to the clinic.

The more specific causes for the delay in these 95 cases may be attributed to the patient's own ignorance of such conditions in 33 instances. In 19 cases it may be attributed to the patient and the physician combined. In 18 cases it may be attributed to the physician alone, and 5 of these were the fault of carelessness or ignorance of the physicians in this institution. This is but a small portion of the total yet these mistakes might easily have been averted had a little more care been taken. It is easy enough to blame outside physicians for failure to recognize or treat a cancer properly when the case finally comes to a large hospital with all its personnel and diagnostic facilities but it is regrettable when a similar inability to make a correct diagnosis (and especially in some fairly obvious cases) is due not so much to ignorance or stupidity of the physicians in a large hospital or medical center but to carelessness on the part of these physicians in failing to do a rectal examination in a case of rectal carcinoma or when the volume of clinic routine and red tape cloud or delay the issue with resultant delay in the patient receiving a thorough and careful examination and early operation.

There were only 11 patients in the total number who gave the fear of cost of treatment as their chief reason for delay. Another group of 10 patients stated that the fear of an opera-

tion was their chief reason for not seeking relief at an earlier date. Only 2 patients in the whole group stated that they delayed because of the fear they might have a cancer.

The average lost time for all these patients studied was exactly 11 6 months. The author has attempted to estimate roughly the amount of delay that might have been avoided in each case. This estimated *avoidable* delay was approximately 7 6 months on the average. If it were only possible to eliminate this *avoidable* delay it would mean that these patients would come to the hospital with an average *unavoidable* delay of only 4 months. It is interesting to speculate on the increased number of operable cases could they be obtained with such a short duration of symptoms.

There is a very striking difference in the results of various cancers treated before and after lymph node involvement has taken place. To mention the group of breast cancers alone, I could do no better than to quote Stout and reproduce the table in his book on *Human Cancer*. In a detailed analysis of all types of cancer operated upon at the Presbyterian Hospital for the ten year period of 1916-1925, inclusive he states that "there were metastases in 53 per cent of those cancers radically removed 1 month or less after discovery and if one year or more had elapsed between discovery and operation we found that 73 per cent showed axillary metastases and 85 per cent later died of generalization."

Stout also states that "if axillary nodes are involved at the time of operation it is an indication that the woman has less than one chance in eight of having had all the cancer removed by the operation for only 12 3 per cent were cancer free after 5 years. Conversely, if there are no axillary metastases found at the time of operation more than one half the cases will survive more than 5 years and nearly one half the cases will be cancer free at that time."

CONCLUSIONS

In conclusion it might be well to repeat that the average total duration of symptoms in this series was 11 6 months a figure identical with that found by Simmons and Daland, and nearly the same as that found in a study

by Farr, namely, 11 9 months. Although it was the purpose of this study to determine the factors causing this delay these factors in themselves would suggest a partial solution for shortening this delay. The fault was found to belong to the patient the physician, or a combination of both in 70 cases in this series, or approximately 74 per cent of the whole group. It would seem, therefore, that anti cancer propaganda for the lay public must be made much more effective if we are to expect patients to seek medical advice at an early date. On the other hand, this will be of no avail, unless even more strenuous propaganda be carried out within the medical profession in order to get the general practitioner to suspect cancer more frequently and to refer the suspected case to a surgeon or hospital well qualified to diagnose and treat cancer. When the *avoidable* delay can be cut down from one half to two-thirds of its present length, then only shall we be able to expect a real improvement in the treatment of patients afflicted with cancer.

CLINICAL SURGERY

FROM THE ST HILDEGARD HOSPITAL

NEW METHODS IN GALL-STONE SURGERY

H O PRIBRAM M.D. BERLIN GERMANY

Professor of Surgery at the University Berlin

THE general rules for operating upon an obstructed papilla do not differ very much in the different clinics of the world. If it is impossible to remove stones through a supraduodenal incision in the common duct, we usually try to extract them through a second incision in the retroduodenal part of the common duct, after extensive mobilization of the duodenum. We do not always succeed with this method either, in which case we resort to the radical method of laying bare the papilla across the duodenum.

Of course, we realize that by the two just mentioned methods, the retroduodenal and the transduodenal, the operative risk increases. The danger in the retroduodenal method lies in the fact that the tissue behind the duodenum has very little resistance to infections of any type. We note very often at postmortem examination a steady increase in infection in the retroduodenal region, in spite of the fact that it may have completely ceased in the intraperitoneal area. The retroduodenal region is also a favorable site for postoperative bleeding in the presence of cholemia.

For all these reasons many surgeons have abandoned the retroduodenal operation completely in favor of the transduodenal route. The transduodenal route also has its drawbacks as we very well know, for it carries a high mortality rate, even if done by an able surgeon of long experience.

The operative risk increases as the infection and cholemia progress. To judge from all large series of cases we are faced with untoward results in 50 per cent of the cases, and the risk is even greater in patients of advanced age. The surgeon is confronted with the knowledge that in spite of a perfectly executed operation he can do little to avoid many imminent complications.

In the following case I tried a new method which proved to be extremely successful, especially in view of the desperate condition of the patient who was in a state of cholemia, and infection was far advanced.

A man of 68 years, had suffered for years with gall stones. He recently had an attack of colic followed by jaundice which lasted for several weeks, and lately he has been having chills. He was brought to the clinic and we found the patient in a very bad general state. Besides sepsis and cholemia he showed signs of an acute peritoneal irritation in the upper abdomen. Our suspicion that this was due to an acute pancreatitis was confirmed by the finding of large quantities of diastase in the blood. To have operated immediately would have given but little chance of success. Ice compresses were applied in the hope of localizing and diminishing the symptoms of general peritonitis. Fortunately the symptoms did decrease during the following days, but a sudden flare up of all symptoms forced us to operate immediately.

I opened the abdomen through a costal incision (Figs 1, 2, 3). A few words about this incision. It lies a little over the costal arch so that the base is formed by the costal bones. We can thus avoid all postoperative hernias with certainty, even in the presence of extensive suppuration. This could be proved during the 10 years this incision has been practiced in my clinic.

After the peritoneum was opened numerous necroses in the fatty tissue were visible. The gall bladder was opened and numerous stones were removed. The badly inflamed mucous membrane of the bladder was quickly electrocoagulated (mucoclasia); the common duct was opened in the supraduodenal area, and many stones were extracted but it was impossible to empty the papilla completely of stones through this incision. To carry on further manipulation by the retroduodenal or transduodenal routes would be taking too great a risk because of the general state of the patient, especially in the presence of acute pancreatitis.

I decided not to operate further at this time so simply introduced a small drain into the common duct, the drain reaching the stones. The common duct was then tightly sewed around the drain. Our idea was that should the patient survive we would try to dissolve the stones by the injection of suitable dissolving liquids by way of the drain. The operation was thus performed very quickly and the recovery of the patient was so satisfactory that, on the fifth day we could begin with our experiment.

Daily injections of several cubic centimeters of ether were made upon the stones. Ether is one of the best soluble liquids for cholesterin. Our intention was to destroy the compact consistency of the stones by dissolving the cholesterin nucleus, thus reducing the stones to a soft pulp which would easily pass the papilla. That this can be done can be proved very easily by mixing the most ordinary bilirubin calcium stones with ether. The stones crumble

¹Pribram. Der Costalschnitt. Deutsche Zeitsch. f. Chir. 1930, 83. Zur Technik d. Costalschnittes bei Gallenperitonien. Zentralbl. f. Chir., 1934 No. 27.

into a sediment of brown, soft pulp, as can be seen in Figure 4. The cholesterol, after having been dissolved in ether crystallizes into white needles after evaporation (Fig. 5). It still remained to be seen whether or not this experiment could be practiced on a patient with the same success.

On the fifteenth day of the treatment it seemed for the first time that not all of the sodium chlorate solution injected returned but that some of it flowed through the papilla into the duodenum. An immediate X-ray examination after the injection of an opaque liquid confirmed my observation.

In Figures 6 and 7 the biliary ducts are seen filled with the opaque liquid, and over the papilla are two distinct spots showing the position of the remaining stones. It will also be noted that some of the opaque liquid has already passed into the duodenum. Another X-ray picture, taken several days later during treatment with ether shows that the papilla has been completely freed and nearly all the injected opaque liquid has passed into the duodenum.

It was now very easy to manipulate the drain through the free papilla into the duodenum (see Fig. 8). We extracted the drain and 3 days later the fistula on the abdominal wall had completely closed.

I have used the ether method in the 4 other patients who were sent to my clinic to be operated upon for papillary obstruction. All these patients were in very poor general condition with advanced choleraemia and sepsis and had been having frequent chills daily. In all of these patients the operation was completely successful. By means of the X-ray I was able to watch the progress of the freeing of the papilla as shown in Figures 9 to 11, 12, 13.

The injection of ether is borne by the patient generally without complaint. It is important, however, that not more than 2 or 3 cubic centimeters be injected at a time and that the tube should be left open after the injection has been completed or else undue pressure would be produced in the epigastrium, as a result of the evaporation of the ether which takes place at body temperature.

The value of this method seems to be twofold. The operation is very simple and can be done quickly; the operative risk, therefore, is greatly lessened as compared with the risk connected with other operative methods formerly in use. This technique seems to be especially indicated in patients suffering with choleraemia and sepsis, when the most simple operation is also the best one.

We use this method in place of the retroduodenal or the transduodenal method not only in cases in which we are unable to free the papilla by simple incision of the common duct, but also in cases in which there is the least suspicion that all the concretions have not been removed. The ether dissolves stones even when they are embedded in the wall of the common duct, a position difficult to reach by mechanical means. This method has proved of value too in the treatment of biliary fistula caused by stones which were

overlooked in the common duct when operation was first carried out.

The introduction of a drain through the fistula down to the stones and the application of ether, cause in a short time the softening and partial dissolution of the stones and their passage through the papilla. Thus a second complicated operation is avoided.

Other surgeons have also reported good results following treatment of biliary fistulas with this method. By means of the X-ray and the injection of iodized oil through the drain we are able to determine with certainty whether the papilla and the common duct are absolutely freed of stones before we remove the drain. The small remaining fistula will then close in about 24 hours.

This procedure will diminish the number of the so called pseudo recurrences.

A prolonged study of the causes of so called recurrences after gall-stone operations has convinced us that a considerable number of these complications are directly or indirectly due to loss of function of the resected gall bladder. Before explaining the new method of procedure, I would therefore like to summarize our findings concerning the function of the gall bladder as well as regarding the pathological and clinical manifestations following the loss of function.

One of the main functions of the gall bladder is to serve as an overflow reservoir equalizing the oscillating pressure in the common duct and regulating this pressure. The liver does not produce bile continually but in certain rhythmical stages bile is poured forth the quantity produced being influenced by nutrition and other external causes. This interrupted secretion of the liver causes changes of pressure in the common duct but within certain limited bounds much greater are the changes of pressure in the common duct produced by the rhythmical contraction of the papillary muscle, the sphincter of Oddi.

These changes of pressure can be studied very easily in a patient with a drain in the common duct. For this purpose the drain must be placed in such a position that its end will lie above the papilla but far enough from it so as not to interfere with the rhythmical play of the sphincter muscle. The wall of the common duct must be sewed tightly around the drain. The quantity of bile flowing out through the drain must be measured every hour.

We very often notice variations in the outflow of bile, the quantity varying from 0-50 cubic centimeters and even more. A large quantity indicates a closed papilla, while if the papilla is open all of the bile flows into the duodenum so

that the outflow of bile stops almost completely. Figure 14 is a curve showing the amounts of bile collected hourly and illustrates well the papillary function. The rise in the curve corresponds to the time when the sphincter was closed, the descent of the curve while the sphincter was open.

These oscillations in pressure are regulated perfectly through the natural function of the gall bladder which fills during the time the sphincter is closed. A constant pressure in the common duct is thus secured. When the gall bladder is destroyed by inflammatory processes, when the cystic duct is closed on account of the presence of stones or when the bladder has been removed by operation, all the unregulated changes of pressure are then transferred to the liver.

Patients usually do not feel the changes in pressure except when the spasm of the papilla lasts a longer time than usual, when prolonged spasms of the sphincter of Oddi are apt to occur. This has been observed in many patients.

That such prolonged spasms really occur I was able to determine clearly by means of the X ray in the case of a woman whose papilla had been absolutely freed. The X ray picture showed all biliary ducts filled with iodized oil with not a single drop passing through the contracted papilla. The spastic contraction of the papilla was maintained during the whole time of the observation, i.e., nearly an hour. After this I made an intravenous injection of 2 milligram of atropine sulphate. When it first became evident that the atropine had taken effect (dryness in the mouth and mydriasis) I made a new X ray picture. The papilla was then wide open and the iodized oil was flowing in a wide stream into the duodenum. (Figs. 15, 16, 17)

The patient whose gall bladder does not function properly feels the spasms as very unpleasant sensations in the region of the liver. His complaints are characteristic: a feeling of oppression in the upper abdomen, belching, nausea, also a temporary enlargement of the liver is noted. Many patients are constitutionally inclined to spasms of all kinds but in addition we know that some external factors may act as irritants and cause spasms of longer duration: cold drinks, gastric and enteric processes with or without ulcerations, constipation and intoxication of alimentary origin.

An unregulated increase of the biliary pressure has a much graver effect in the presence of latent hepatitis: here reactivation of the hepatitis manifests itself in enlargement of liver due to oedema, increase of temperature, and even jaundice.

We find such attacks of hepatitis fairly often in

Fig. 1. Costal incision

the recurrent case. Critical observation of these cases shows that the flare up of such types of hepatitis has become more frequent after operation.

We must therefore conclude that in these cases the hepatitis has been aggravated by the cholecystectomy. The explanation of this fact is easily found if our previous statement is recalled: the gall bladder the function of which is to regulate the bile pressure and to prevent stasis, is missing. In a certain sense the gall bladder acts as an organ to protect the liver. In addition, another fact should be mentioned: after the gall bladder is resected we find that the inclination of the sphincter of Oddi to spasms has in many cases increased and especially if the patient is constitutionally inclined to spasms generally.

The nervous regulation of the gall bladder and of the sphincter of Oddi are so connected that tonic contraction of the bladder is associated with the opening of the sphincter, whereas a contraction of the sphincter is co-ordinated with distention of the bladder. Such nervous connections are found in most organs limited by a sphincter: for instance the oesophagus, the urinary bladder, etc. I wish especially to emphasize the relation between the pathological narrowing of the cardia and the dilatation of the oesophagus. That relation is not simply the result of cause and effect but is based on common nervous disturbances. Removal of the gall bladder destroys the complicated nervous mechanism which regulates the bile ducts, and thus is produced a disturbance which in many patients is manifested by an increased inclination to spasm. The increase of pressure as a result of the absence of regulation and the stasis in the bile ducts has a noxious effect upon the latent infection of the liver.

These disturbances of nervous regulation after cholecystectomy are not manifested in all patients

Fig. 2

Fig. 3

by a cramp of the sphincter sometimes—and this is the second form of disturbance after loss of function of the gall bladder I wish to mention—a pronounced insufficiency of the sphincter is noted which causes a permanent flow of bile into the bowel.

These atonic forms of disturbances, as we shall call them, have their own clinical symptomatology—intestinal disturbances, ranking foremost inclination to enteritis and diarrhoea—a diminished stomach secretion up to the point of complete achylia, etc. I have not the space here to enter into a discussion of all of these interesting problems but I would like to mention the fact that we found that the use of pepsin and chloric acid was a means through which the intestinal disturbances which follow cholecystectomy may be overcome.

Fig. 4, left. Dissolution of gall stones in ether

Fig. 5. Dissolved cholesterol crystallizing, the ether having evaporated

The gall bladder has still other functions of which I should like briefly to mention only a few. The concentrated bile of the gall bladder contains in large quantities activators for the digestion of fat. These activators are of the greatest importance therefore the patient who has had his gall bladder removed is handicapped in the digestion of his food, especially of fat.

In addition, the gall bladder is an organ which probably produces in its mucous glands substances of hormonal character which have a great influence upon appetite and palate enabling one to discern and appreciate the different food-stuffs. I will later return to this subject.

Our experiences have therefore led us to be more conservative than formerly in resecting the gall bladder. We now resort to cholecystectomy only in those cases in which the gall bladder has been completely destroyed and its function therefore completely lost. Moreover we are confronted with a new problem not only to conserve the bladder but to restore its lost function if possible.

This problem led us to search for an operative method which would fulfill all the conditions which have been mentioned—the conservation of the gall bladder and at the same time the complete removal of gall stones, the avoidance of all recurrent troubles, the result of the loss of gall-bladder function, which function should be restored by operation. The operative methods designed to conserve the gall bladder which have been in use until now—cholecystotomy and cholecystostomy—do not by any means attain this end.

The follow up of patients who have been treated by cholecystostomy—an operation used rarely and only in special cases—has shown extremely bad results. We are not alone in the observations of these facts. I here mention particularly the

Fig. 6

Fig. 7

Fig. 8.

statistics of Whittaker and Spurling of Boston. Of the 12 cases observed, 5 patients had grave recurrent colics, 4 minor disturbances of different kinds, 1 had no liver symptoms but had a post-operative hernia, 2 patients only were without complaints. It should be mentioned, however, that these 2 cases had been followed for a period of only 25 days after operation. Six patients, that is half of all the cases, had to have a second operation. Four of these showed the formation of new stones, 1 had an acute necrosis of the pancreas, and all of them showed signs of cholecystitis.

Therefore, not only the danger of real recurrence, i.e., the formation of new stones in the gall bladder after cholecystostomy, is a big one

but there are still other complaints. All facts led us to believe that cholecystostomy does not secure the result hoped for and therefore should be avoided.

The conditions which must be fulfilled in any operation to conserve the gall bladder are the following. In the first place, one must be sure to avoid every possibility of stasis in the gall bladder—the free outflow of bile from the bladder must be guaranteed. Stasis in the presence of infection is the main factor in the formation of new stones. Cholecystoduodenostomy and cholecystogastrostomy are also designed to avoid stasis in the gall bladder in that they include permanent drainage. Statistics showing the experiences of the later

Fig. 9

Fig. 10.

Fig. 11

Fig. 12

Fig. 13

results of this operation as published recently by many surgeons are not encouraging, however.

After a certain time it is found that nearly always a grave infection of the gall bladder follows the anastomosis with the bowel, an infection which not only revives the former symptoms of cholecystitis but also gives rise to an ascending cholangitis.

Cases have been observed in which, for instance after the gall bladder has been anastomosed with the stomach, the gall bladder had become a reservoir for remnants of food, thus causing very grave disturbances necessitating radical secondary operation. Such a case has recently been described by Enderlen. For all the reasons given we cannot use this operation in the presence of gall-stone diseases with the purpose of conserving the bladder.

I shall now discuss an operation which seemed to me to be worthy of trial. It insures the free drainage of the gall bladder not by anastomosing it with the bowel or the stomach, but by effecting a wide anastomosis between the gall bladder and the common duct (Fig. 18). In this way the sterility of the bladder is preserved in spite of the very free outflow of bile; at least the bacteriological medium is not changed for the worse. At the same time the conditions for the healing of the inflammatory processes in the bladder are improved as the possibility of stasis is avoided.

Experiments have shown that the tendency of the gall bladder to heal after inflammation is not so small as we had thought. The gall bladder moreover is conserved with all its functions to regulate pressure and with all its normal secretion. It is really astonishing that, in spite of the clear

logic of this operation, it has not previously been done.

It has always seemed to be the method of choice to operate upon a gall bladder with stasis (*Stagnationsgallenblase*). The first case in which I attempted this new technique cholecystocholedochostomy is an illustration. The history is interesting enough to be given in full.

A woman, aged 34 years, had suffered for 3 years with pain under the right costal arch, nausea, and vomiting. She had been operated upon by another surgeon 2 years previously on the suspicion of gall stone disease. There had been no pathological findings except a spastic contraction of the pylorus. For this reason a pyloromyotomy was cut through the muscle of the pylorus, had been performed.

After the operation not only no improvement but a turn for the worse could be observed, manifested by a feeling of oppression, vomiting, and decrease of weight. The patient was rendered incapable of carrying on her professional duties and was sent to my clinic. The patient, very much reduced in weight, told us that for nearly a year she had not been able to eat anything without a feeling of fullness shortly afterward. She showed an intolerance of all food not only of fat but also of meat and carbohydrates of all kinds. She could take only small quantities of food and remained in bed nearly all day. We found a distinct tenderness under the right costal arch. The suspicion that the complaints were due to ptosis of the stomach was not confirmed by the X-ray examination. Cholecystography revealed a badly filled bladder but of clear outline, emptying slowly.

Operation was done under spinal anesthesia. The gall bladder was enlarged, was under much tension, and could not be emptied by pressure. The wall was thin and showed no signs of any grave inflammation. Adhesions between the neck of the bladder and the hepatoduodenal ligament caused a kink in the extremely long cystic duct. The bile secured by puncture showed the typical dark green color characteristic of that when stasis is present. I now effected, in the manner mentioned, a wide anastomosis between the neck of the bladder and the common duct.

Fig. 14. Curve showing contraction of the papilla.

The effect of the operation was remarkable. The symptoms vanished almost immediately and the patient became astonishingly hungry within a few days after the operation—a surprising contrast to the constant lack of appetite before the operation. The farther recovery of the patient was very rapid and she was able to eat any kind of food. Increase of weight was 15 pounds within a short time. During the whole time of further observation she never had any complaints.

To illustrate the improvement of the reabsorption of food further I should like to describe some experiments I made with this patient. It is known that for the digestion and the best reabsorption of fat not only the lipase of the bowel is needed but also the bile which increases the work done by the lipase in the sense of an activator.

According to our study the bile of the liver does not act nearly as effectively as does the bile of the bladder. The activating effect of the bladder bile sometimes surpasses the measure which could be expected from a more highly concentrated bile. From this fact it must be logically concluded that the bladder produces still other activating substances which perhaps are secreted by the glands of the gall bladder wall. And now to return to the experiments which were made in the case referred to.

Findings before the operation. In the duodenal juice large quantities of lipase were noted, but the activating effect of the duodenal bile was only slight. Digestion of fat was very poor. This was proved by the lack of a normal increase in the curve showing the bloodfat in the culminating point of digestion. Figure 19 shows a normal curve for blood fat during digestion with an increase in the culminating point nearly in the sixth hour after a meal. For comparison Figure 20 shows a flat curve which indicates poor reabsorption of fat. The activating value of the bile of the bladder secured by puncture during operation was extremely high.

To sum up in spite of the fact that the duodenal juice contained a normal quantity of lipase and in spite of the fact that the activating value of the bile of the bladder was high, the activating value in the duodenal juice was very low. The digestion of fat was very poor as could only be expected when we realize that the bile of the bladder could not flow freely into the duodenum and thus its activating effect was lost.

After operation i. e., after relief of stasis in the bladder and after the establishment of free drainage of the bile of the bladder into the duodenum the duodenal juice obtained through a duodenal tube showed in contrast to our former finding a high activating value. Tolerance and digestion of fat became quite normal. This could be demonstrated by the presence of a normal curve as to blood fat. The favorable effect of all this on the patient has already been mentioned: an increase in appetite and a gain in weight within a short time.

Encouraged by the excellent result in this first trial I used the operation in several other cases with the following modifications in technique.

Fig. 15

Fig. 16

Fig. 17

Fig. 15 Sphincter muscle in contraction.

Fig. 16 Ten minutes later after having injected 3 cubic centimeters atropine. Sphincter begins to open itself.

Fig. 17 Few minutes later. The sphincter is now widely opened. There is present a free outflow into the duodenum.

The region is laid bare through the costal incision described. The gall bladder is punctured and its liquid contents are removed, and the bladder washed out with a solution of sodium chlorate. After the anterior wall of the common duct is prepared and after the small blood vessels which are nearly always found in this part are ligated, the common duct is opened through an incision 2 to 3 centimeters long. Calculi if found are removed and it should be determined definitely that the papilla is perfectly free. Then the bladder is opened in the upper interior wall by an incision just wide enough to remove all stones present. A new incision is then made in the neck of the bladder, the incision being made the same length as that in the common duct. Two catgut sutures fix the ends of both incisions and draw together the walls of the common duct and the bladder. While the assistant distracts the two holding sutures, suture of the posterior part of the anastomosis can be done very easily. In the same way suture of the anterior part of the anastomosis is perfected. The suture line is protected by serous tissue from the neighborhood, especially from the hepatoduodenal ligaments.

When signs of more grave inflammation in the bladder are noted or when many small stones are found, it is advisable, before the anterior suture is completed, to introduce through the bladder and the anastomosis into the common duct, a small drain with several lateral holes, the drain to head toward the papilla. This drain has a double purpose: (1) on the days following the operation the common duct and bladder can be washed with a

solution of sodium chlorate or a solution of nitrate of silver which has proved its value in treating inflammation of the bladder. (2) In the presence of stones which could not be entirely removed it is possible to carry out the other treatment described. Around this small drain conducted outward the incision in the bladder is tightened with sutures. Another larger drain, which can be removed on the third day, is securely placed near the region of the anastomosis. Sometimes bile is found to flow out for 2 or 3 days after operation.

At first I used this technique only in cases in which, aside from the finding of stones, no remarkable pathological changes had taken place in the wall of the bladder.

In view of the excellent results obtained in these cases I decided to use the method also in cases in which the gall-bladder walls were badly inflamed and in those in which the bladders were hydropic. Only those in which the wall of the bladders were totally destroyed and those in which abscesses were present were eliminated. In these latter cases mucoclasia¹ should be performed.

In this way I was able to conserve the bladder in the majority of patients brought to my clinic. Of 22 patients thus operated upon I did not have a single mortality. The recovery in all of the patients was excellent, in fact less complications were encountered than after the best cholecystectomy.

First of all, on the third or fourth day after the operation a surprising but common sequel is noted.

Fig. 18.

patients develop an appetite which sometimes increases to the point of a pronounced feeling of hunger. It is a well known fact that this does not occur even when patients make the best recovery after cholecystectomy. Food tolerance after cholecystectomy is diminished for weeks and months and for good reasons the rule that a strict diet be prescribed is observed. I have often made the interesting observation that cholecystectomized patients complain that all food has the same taste and that the gift for discerning the taste of different foods becomes less pronounced after the loss of the gall bladder.

Quite different is the story of the patient who has been treated with cholecystocholedochostomy. The patient shows not only as mentioned, an appetite extraordinary for the third or fourth day after operation but in the first week he tolerates

Fig. 20. Curve showing bad reabsorption of fat.

Fig. 19. Normal curve, good reabsorption.

food much better than could be expected from his condition before operation.

I have observed patients whose tolerance for food had become so poor during the course of the gall-stone disease that they could not only not tolerate fat but even meat and eggs could not be eaten. On the fourth day after operation, however, these same patients were able to eat food of every kind, a thing they had not been able to do since the beginning of their illness.

I wish particularly to emphasize the food question, the increase in tolerance for food being one of the most interesting and most common sequel after cholecystocholedochostomy. This fact does not seem so extraordinary when we recall our experiments concerning the function of the gall bladder and the activating importance of the bile of the gall bladder.

The number of patients operated upon by this method and the period of observation is too short

Fig. 21. Effect of activators. Mixture of pancreatic lipase of distinct titre with oil emulsion.

(the first case being under observation for a year) to enable us to form a definite opinion of the value of this new operation. To be able to say something really definite we should have not only thousands of cases but our study should be carried over several years. We must remember that 50 years have elapsed since cholecystectomy came into use and it is only recently (see especially the report of the Congress in 1932 at Vichy concerning the end-results of cholecystectomy) that doubts have been expressed as to the advisability of removing a functioning gall bladder.

At any rate, based on the excellent results I have obtained, I believe that this operation merits further investigation. One fact I believe should be stated: cholecystocholedochostomy seems to be the most logical operation to use in cases in which the gall bladder is in a state of stasis.

One other thing should be mentioned: surgeons and physicians all agree that the chances for favorable results of the operation are best when the patient is operated upon in the early stages of the disease rather than when the disease has progressed. However the arguments of physicians and surgeons against operation performed in the early stages concern principally (aside from the operative risk) the early removal of the gall bladder and the fact that at times there is a remarkably high percentage of recurrent complications.

If by operating at an early stage, we are able to avoid recurrences by conserving the gall bladder with its complete function and, more than this, if we can overcome disturbances in function we should be more emphatic in insisting upon the necessity of an early operation.

THE INCIDENCE OF GASTROJEJUNAL ULCER FOLLOWING GASTRO-ENTEROSTOMY¹

J WILLIAM HINTON M.D., F.A.C.S. NEW YORK

Associate Professor of Surgery New York Post-Graduate Medical School (Columbia University) Associate Visiting Surgeon, Bellevue Hospital

REYNOLD E. CHURCH M.D. NEW YORK

Instructor in Surgery New York Post-Graduate Medical School (Columbia University); Assistant Visiting Surgeon, Bellevue Hospital

THE ever perplexing question as to what percentage of patients develop gastrojejunal, or marginal ulcers, following a gastro-enterostomy, creates as much controversy now as when partial gastrectomy was advocated a decade ago to eliminate this serious sequela of a gastro-enterostomy. The incidence of marginal ulcer was found so high in some clinics it was thought that the routine gastro-enterostomy should be discontinued and the more radical procedure partial gastrectomy, done. In 1925 Lewisohn published a paper in which he studied 68 patients and found 34 per cent of gastrojejunal ulcers in their clinic. His paper brought forth considerable discussion and men in numerous clinics felt that a gastro-enterostomy was rarely followed by a marginal ulcer. A recent paper by Gaitner in which he studied 100 cases and found the results most satisfactory, would indicate that there is still considerable difference of opinion as to how frequently gastrojejunal ulcer is seen following gastro-enterostomy.

We feel that the results from gastro-enterostomy in the Gastro-Enterological Clinic of the Fourth Medical and Surgical Division of Bellevue Hospital should be recorded. Our clinic is now over 6 years old and we have had the opportunity to study some cases for a long period, therefore we wish to report the cases of gastro-enterostomies entering the clinic from January 1, 1928 to January 1, 1933. During this period we have admitted 583 cases of peptic ulcer, and of this group 440 cases were unoperated upon at the time of admission which leaves only 143 cases that were operated upon before entering the clinic. Of the 143 patients who had been operated upon before entering the clinic, 90 had been operated upon for chronic ulcers, and 79 of these had had gastro-enterostomies performed. We will consider only the 79 cases having had gastro-enterostomies, and of this group we have encountered 13 patients with gastrojejunal ulcers which is 16.4 per cent of marginal ulcers occurring in the gastro-enterostomies during the 5 year period.

Before going into a detailed discussion of the cases we wish to present it would seem worth while to call attention to the fact that our clinic

has been run for the purpose of closely observing patients suffering from peptic ulcer to see what the final results are from the different methods of medical and surgical treatment. During the 5 year period from January, 1928, to January, 1933, 583 patients observed in our clinic made a total of 9,567 visits which would average 16.2 visits per patient for the 5 year period, or 3.2 visits per patient per year. It is important, in drawing conclusions from patients treated for a peptic ulcer, to have frequent observations as to his clinical course, otherwise conclusions are most inaccurate. From the observations in our clinic we feel that a follow up letter is more misleading than helpful in drawing conclusions in ulcer patients. Also any report based on a single observation after one to several years have elapsed, following operations, is also misleading. It is known that the symptomatology of a peptic ulcer runs in cycles, and unless there are frequent periods of observation of the clinical course, this periodicity may be lost and the patient seen in the interval will be symptom free and frequently forgets the discomfort he has suffered a few months before. We would like to call attention to the fact that we have carefully selected the patients that have been referred from our clinic for operation, and of the 583 cases 440 as previously stated, were unoperated upon at the time of being registered in the clinic and of this number we have referred only 33 patients for operation during the first 5 years, which indicates that we have tried to select the patients for operation with the greatest possible care.

To illustrate the seriousness of gastrojejunal ulcer we wish to report a case which came under our observation during 1933 and which is extremely interesting. In this case the gastrojejunal ulcer followed a gastric resection and is not included in our percentage figures, as we are including only those that followed gastro-enterostomy. The case is presented merely to impress the seriousness of a marginal ulcer.

Male, 37 years of age, admitted to the clinic February 16, 1933 having been discharged from the hospital's days before, after being operated upon for a perforated gastrojejunal ulcer. The patient first had pain in his stomach in

¹Read before the American Gastro-Enterological Association on April 30, 1934, Atlantic City, New Jersey.

1928, associated with nausea and vomiting after meals. At the time a diagnosis of duodenal ulcer was made and the patient was placed on a Sippy diet. His condition improved but 6 months later he collapsed on the street and was taken to St. Mark's Hospital with a severe hemorrhage. The patient was transfused and later operated upon in that institution and a resection of the stomach done with a Polya anastomosis for an ulcer of the duodenum. The patient felt well until 5 years later or in 1930, when he had a severe hemorrhage from his stomach and was again referred to the same hospital and at this time he was transfused. Following this he felt well, although he had slight abdominal pain until May 1932 when he had a sudden severe pain which caused him to collapse and he was referred to the Peoples Hospital and operated upon for a perforated ulcer in the jejunum, one inch distal to the anastomosis. The perforation was closed, and the patient made an uneventful recovery and felt well for about 3 months. In January 1933, however, he began having pain in his abdomen which was fairly severe and on January 30, 1933 he was seized with sudden severe pain in his abdomen and was sent to Bellevue Hospital. The operation revealed at the gastrojejunal anastomosis a perforated ulcer of the jejunum one-half inch from the margin of the anastomosis on the jejunal end and the perforation was about one-quarter of an inch in diameter and surrounded by plastic exudate. The perforation was sutured but due to marked linkage it was necessary for the operating surgeon to do an entero-enterostomy between the proximal and distal loop of the jejunum.

The patient was seen in the clinic 3 times during the early part of 1933 and was last seen on May 3, 1933 when he felt quite well and had been symptom free for 3 weeks. X-ray series were purposely not ordered immediately following his operation due to fear of additional trauma from manipulation at the site of the anastomosis. This patient, of course, illustrates a very dramatic picture of what can happen from a peptic ulcer in spite of the fact he was receiving medical treatment for his ulcer when the first hemorrhage occurred. For anyone to offer a prognosis on this case would be mere speculation and the case is presented to illustrate the seriousness of gastrojejunal ulcer.

CASE. Male Russian Jew 53 years of age admitted to the clinic, July 4, 1925. Before admission to the clinic he was complaining of abdominal pain after meals which would come on 2 to 3 hours after eating and it would bother him at intervals of few weeks to few months at a time, although he had been operated upon 3 times for ulcers of his stomach. Patient was first operated upon in 1912 at Beth Israel Hospital, New York City for a duodenal ulcer. Previous to his operation he had had ulcer symptoms for one year and had had medical treatment for his ulcer without relief of his symptoms and operation was advised. A gastro-enterostomy was performed and the patient was well for 6 months after which he began having severe pain which was similar to that preceding his operation but more severe. He was under medical treatment and very little relief was obtained from his symptoms. X-ray series on December 17, 1925, revealed a duodenal ulcer but otherwise negative. Patient first entered Bellevue Hospital December 16, 1925, and was discharged January 3, 1926. He was operated upon December 30, 1925. At operation the omentum and stomach were found adherent to the anterior abdominal wall with the transverse colon fixed to the site of gastro-enterostomy. The duodenum revealed healed ulcer one inch distal to the pylorus. The gastro-enterostomy was placed high on the posterior wall of the stomach with a jejunal ulcer one half inch from the stoma on the efferent loop of the jejunum, penetrating into the transverse colon. The ulcer was excised from the jejunum but its base was

left attached to the transverse colon, and carbolized and inverted. The gastro-enterostomy anastomosis was dissipated and the stomach wall closed with 2 layers of No. 1 chromic catgut. An end-to-end anastomosis was done in the jejunum No. 1 chromic being used for the closure. Convalescence was uneventful, patient was seen regularly in the follow-up clinic and on March 7, 1926, he had gained 18 pounds in weight but was having an occasional burning sensation after eating but was following his diet regularly. The patient was seen at monthly intervals during April, May, June, July, August, and September and during all of these visits complained of slight abdominal discomfort but no typical ulcer pain. On his last visit October 3, 1926, he had gained 23 pounds. He failed to return to the follow-up clinic and on September 4, 1927 could not be found at his previous address. He was re-admitted December 17, 1927, complaining of a burning pain in the epigastrium, belching of gas of a few days' duration. X-ray series December 18, 1927, revealed a duodenal ulcer. Patient was again operated upon December 23, 1928. There was found an ulcer in the first portion of the duodenum on the anterior superior surface and marked adhesions in the right upper quadrant but the site of the former gastro-enterostomy was inspected and there was no evidence of obstruction to the jejunal anastomosis. The duodenum was separated from the under surface of the liver and the ulcer was infolded with No. 3 chromic pursestring sutures but not excised. The patient made a rather stormy convalescence, developed pneumonia in the right lower lobe, following which he developed empyema. He was operated upon February 18, 1928, for an empyema of the right chest and the eighth rib on the posterior axillary line was resected. He made an uneventful convalescence and was discharged from the hospital March 9, 1928. After coming under our observation July 4, 1928, patient continued to have abdominal discomfort but returned to the clinic at irregular intervals, although he was instructed to return at weekly intervals he came back at periods of 3, 4, to 6 weeks. He was put on a Sippy diet when he first entered the clinic and given saline subcutaneously. X-ray series on June 14, 1929, revealed an ulcer of the first portion of the duodenum, no 6 hour gastric retention. In spite of these findings he returned for treatment rather spasmodically and on September 20, 1929, he entered Post-Graduate Hospital and was operated upon for an ulcer of the duodenum. Report from that institution was as follows: "Diagnosis: Pyloric ulcer with obstruction, and marked gastric dilatation. Operation was posterior gastro-enterostomy although there was a definite mass in the region of the duodenum, which was practically impossible to free due to the denseness of adhesions in that region. Patient was discharged from that institution on October 10, 1929." Since then we have seen him in our clinic November 23, 1929, August 7, 1930, August 21, 1930, November 6, 1930, November 20, 1930, July 9, 1931, and July 16, 1931. During all these visits he stated he felt quite well and was following his diet very regularly but has had occasional abdominal discomfort but no real pain simulating an ulcer. X-ray series November 12, 1930, revealed an ulcer of the first portion of the duodenum and a gastro-enterostomy with a normal appearing stoma. X-ray series July 13, 1931, revealed a normal, well functioning gastro-enterostomy with no evidence of a marginal ulcer. He returned to the clinic on November 1, 1931, stating that he had been in his severe abdominal pain for month. A gastro-intestinal X-ray series revealed that there was gastrojejunal ulcer. He returned for treatment for 1 month and felt improved and discontinued.

It can be seen that this patient was most unco-operative but he had 2 gastro-enterostomies per

formed and each has been followed by a gastrojejunal ulcer

CASE 2 Male, Italian, aged 24 years, admitted to the clinic January 21, 1928. Patient had been operated upon in Bellevue Hospital in December of 1927 for an ulcer. Abstract from the hospital was as follows: Patient had been having epigastric pain since July 1927 which was relieved by food, but would return at 1 to 2 week intervals, and then he would be symptom free for an equal length of time. Occasionally he would be awakened at night by epigastric discomfort which was immediately relieved by the taking of food. X-ray series December 19, 1927 revealed an ulcer of the first portion of the duodenum but no 6 hour residue. Operation December 20, 1927 revealed an ulcer in the first portion of the duodenum just distal to the pylorus, with a definite crater in the ulcer but no other intra-abdominal pathology. A posterior gastro-enterostomy was done. No 1 chronic catgut being used for the anastomosis, and a routine appendectomy. An uneventful convalescence was made and the patient was put on a fourth week Sippy diet on his first visit to the clinic. On March 10, 1928, he complained of some gas in his stomach after eating but felt better than before his operation and on April 25, 1928, he felt well and had no complaints. On June 9, 1928, however he was complaining of pain in the epigastrium, of a burning nature. X-ray series on June 21, 1928, revealed the presence of a deformity in the first portion of the duodenum, and an irregularity of the stoma with a niche on the jejunal side of the stoma. On June 23, 1928 patient states he had a different pain in his abdomen from that before his operation. It usually started to the left of the umbilicus and goes to the right side, and the pain had been present for about 8 weeks and had gradually become worse. He was advised to reenter the hospital for operation and after 3 weeks of dietary regimen, without improvement, he was re-admitted July 20, 1928, for operation with the following findings: Adhesions were found between the duodenum and anterior abdominal wall and on inspecting the previous gastro-enterostomy there was found an area of induration on the efferent loop which was adherent to the colon. This was separated. There was also a perforation extending partly through the walls of the colon but it did not involve the mucosa. The gastro-enterostomy stoma was dissociated, the ulcer of the jejunum excised, and an end-to-end anastomosis done in the jejunum. The duodenal ulcer was still present and apparently showed no signs of healing, so a partial gastrectomy was done, and an anti-colic anastomosis was made following the Polya-Balfour technique. Following the operation the patient developed pneumonia and in spite of this made a very smooth convalescence for the first 4 days and then became quite ill and died on July 26, 1928, from a lobar pneumonia.

In reviewing this case one could criticize the operating surgeon for having operated upon the patient without adequate medical treatment. The patient never had any systematic medical management and was also quite young, only 24 years of age. The marginal ulcer developed within 6 months following his original operation and he was re-operated upon 1 month after the diagnosis was made. One could, in view of our present knowledge, question the advisability of operating upon the patient for a marginal ulcer without having given him more prolonged medical treatment for the relief of his symptoms.

CASE 3. Male Russian Jew 39 years of age, admitted October 20, 1928 with a history of having been discharged from Bellevue Hospital after an operation for an ulcer of his stomach. Résumé of the hospital record is as follows: Admitted September 19, 1928, discharged October 20, 1928. Past history: Patient had had an appendectomy in 1913 for chronic abdominal pain and his present history was that for the past 5 years he has had epigastric distress with heartburn 3 to 4 hours after eating. These symptoms were rather mild until 1 year ago when the epigastric pain became more severe and occasionally awakened him at night. He has been under the care of different physicians without relief of symptoms. X-ray series made on September 26, 1928, were negative for an ulcer of the stomach or duodenum, but in spite of his negative X-ray series this patient was advised to have an operation which was done on October 6, 1928. At operation the gall bladder was found to be normal but there was a definite ulcer on the posterior wall of the first portion of the duodenum just beyond the pyloric ring with stripping of the peritoneum, and an indurated area one-half inch in diameter. Operation consisted of a posterior gastro-enterostomy without clamps, the anastomosis between the stomach and jejunum being done with No 1 chronic gut. Routine appendectomy was performed and the abdomen was closed in anatomical layers. On November 24, 1928 about 1 month following his discharge from the hospital, the patient was complaining of pain in his upper abdomen but without definite relation to meals. He was following a fourth week Sippy diet but on December 29 the patient complained that for the past 2 weeks the same pain had been present as before operation. The pain came on before meals and was frequently relieved by food but although an X-ray series on November 21, 1928, revealed the stoma to be normal he continued to complain of pain. X-ray series February 14, 1929 and May 3, 1929 were both negative for a gastrojejunal ulcer but, in spite of the negative X-ray findings, the patient continued to complain of pain similar to that preceding his operation. This patient was given different treatments, including salin, subcutaneously at weekly intervals over a period of months, without any relief. The treatment was then changed to Saunderson's streptococcus vaccine, subcutaneously with very little improvement and X-rays January 17, 1930, revealed the presence of a jejunal ulcer with the presence of a niche formation, with localized tenderness at the site of the anastomosis. X-ray films taken September 17, 1930, revealed a small niche present just distal to the stoma on the efferent loop, with a localized tenderness at this site characteristic of a jejunal ulcer. His symptoms persisted and he was put on gastric mucin in May of 1931 having been given all other known treatment without any improvement, in spite of the fact that the patient was very conscientious in following his regimen. X-ray series January 17, 1932 revealed just distal to the site of the anastomosis a small niche on the efferent loop of the jejunum with localized tenderness at this area, characteristic of a jejunal ulcer. His symptoms persisted and he was re-admitted to the hospital August 4, 1932 and discharged August 23, 1932 after 9 days of bed rest, with a strict Sippy regimen. In spite of treatment the symptoms have persisted and X-ray series April 26, 1933 revealed the presence of a small niche in the efferent loop of jejunum near the stoma suggesting the presence of a jejunal ulcer with localized tenderness over this area. The patient was last seen March 10, 1934, at which time he still complained of some discomfort but if anything he had felt better during the past 4 months than any similar length of time since his operation.

We wish to call attention to the fact that this patient has been carried along under medical

treatment for the past 5 years and if anything he has been better for the past 12 months than any time since his operation, but what the ultimate outcome of this case will be time only can tell

CASE 4. Male, Russian Jew age 63 years, admitted April 11, 1930. This patient entered the clinic on a follow up letter, he having been previously operated upon in 1922. At the time of admission the patient had no complaints referable to his ulcer and he stated that his only complaint was constipation and occasional gas after meals, and if his bowels moved he felt perfectly well and had no complaints whatsoever. The patient had felt well since his operation some 7 years previous. Previous admission. Admitted to Bellevue Hospital October 31, 1912, discharged November 16, 1912. At the time of his admission to the hospital he complained of epigastric discomfort and constipation for 15 years. The abdominal pain came on 3 to 4 hours after eating and the intake of food and bicarbonate of soda relieved his discomfort. In the early years of his disease he had remissions of pain for months at a time but for the past year a strict diet and bicarbonate of soda has given him very little relief of his symptoms. X-ray series revealed an obstructive duodenal ulcer with dilatation of his stomach. An operation, November 3, 1922, revealed there was an ulcer of the first portion of the duodenum which was large and indurated; there was also evidence of a peritonitis about the right upper quadrant. A posterior gastro-enterostomy was done, No. 1 chromic gut being used for the anastomosis. No clamps were used. A routine appendectomy was also done. At the time of admission to the clinic April 11, 1930, the patient's complaint was constipation and he was put on a diet for this. He was referred for X-ray series and barium enema and on May 24, 1930, gastro-intestinal series revealed persistent deformity of the inner and outer part of the first portion of the duodenum with normal gastro-enterostomy stoma, and without evidence of a niche or localized tenderness. The barium enema on June 18 reported no organic lesion of the colon. In the early part of June the patient began complaining of slight epigastric discomfort, but in view of the negative X-ray reports this was discounted to a great extent and treatment was continued for his constipation. On August 17, 1930, he complained of quite severe pain in the epigastrium and he continued to complain of this for the next 3 months, although he was put on a fourth week Sippy diet and was given solin subcutaneously. X-ray series December 3, 1930, revealed a niche just distal to the stoma in the efferent loop of jejunum with localized tenderness. Diagnosis: Jejunal ulcer. X-ray series on February 1, 1931, revealed the presence of a jejunal ulcer with a small 6 hour residue, at the site of the anastomosis. The patient at this time was complaining of severe pain and he had been under the care of one of the internists of the clinic since his admission in April of 1930. March 1, 1930, the patient was turned over to the surgical group by the internist stating that no further relief could be gotten from medical management and operation was advised. At this time he was again put on ambulatory Sippy diet and returned 1 week later stating that he was greatly improved. At this time he was also put on solin 2 cubic centimeter subcutaneously, and had no complaints until October 9, 1930, when he had a slight epigastric discomfort. This he complained of until November 3, 1930, when his pain again entirely disappeared. X-ray series July 30, 1930, revealed the presence of a deformity of the duodenum characteristic of an ulcer but the jejunal ulcer previously visualized was not seen at this time. Re-examination was advised, and X-rays on August 14, 1930, showed a normal functioning gastro-enterostomy stoma, with no evidence of

a niche in or about the stoma. The patient remained perfectly well until December 17, 1931, when he returned, stating that he had slight pain for 3 weeks and X-ray series March 25, 1931, failed to visualize the jejunal ulcer previously reported. X-rays December 14, 1931, revealed an ulcer at the pyloric ring but no 6 hour retention and a normal stoma. At this time the patient was put on Saunderson's streptococcus vaccine, intravenously starting with 50,000 at the first injection and increased 25,000 weekly. On January 24, 1932, the patient was perfectly well, and since January 1932 the patient has been free from symptoms and was last seen December 27, 1932, when he stated that he had felt perfectly well for the past year and a half. X-ray series done May 4, 1932, revealed the presence of a duodenal deformity with a normal stoma and no evidence of niche formation or localized tenderness could be demonstrated.

It is worth while noting that in this patient his operation was done in November of 1922 and he was symptom free until June of 1929, except for constipation. His X-ray series was negative in May of 1929 for a marginal ulcer but a gastro-jejunal ulcer was demonstrated in December of the same year, or 7 years following his gastro-enterostomy. It is interesting to note that this patient had been given up by the internist in the clinic as a medical failure, and after giving him another trial with a Sippy regimen his symptoms disappeared in about 6 months after their onset. With the exception of 2 slight flare-ups, one in October of 1930, or 6 months after he had been entirely free from symptoms, and another in December of 1931 after he had again been free from symptoms for a year's time, this patient has been entirely well. From his repeated X-ray examinations it is certain this patient developed a gastro-jejunal ulcer and this type of ulcer can run periodically as does a peptic ulcer.

CASE 5. Male, American, age 33 years, admitted to the clinic March 20, 1930, complaining of pain in the epigastrium. He had been treated in the medical wards of the hospital for a marginal ulcer from March 8, 1930, to March 20, 1930. A review of the hospital records revealed that in 1928 he had been operated upon for a duodenal ulcer and a gastro-enterostomy had been performed in the Greenwald Hospital. Previous to the operation he had had epigastric discomfort after meals for a period of 3 years. Following the operation for a period of 4 months he had felt greatly improved but then the pain had returned and for 4 months before admission to Bellevue Hospital he had had tarry stools and had vomited blood for a 3 day period. X-ray series March 21, 1930, revealed the presence of an ulcer in the efferent loop of the jejunum, just distal to the site of the stoma, with the duodenum deformed and a small 6 hour gastric residue present. He was placed on a Sippy regimen and referred direct to the clinic on leaving the hospital. At the time he entered the clinic he was placed on Saunderson's streptococcus vaccine intravenously 25,000 bacteria being administered at the first injection and the amount increased 25,000 a week, so as to avoid any reaction. Immediate relief of pain was attained after entering the clinic and there were no complaints until August 7, 1930, when he complained of some abdominal discomfort which lasted until September

11 when it entirely disappeared. X-ray series August 13, 1930, revealed a small niche distal to the stoma in the jejunum, with localized tenderness at this area, characteristic of a jejunal ulcer. The patient had no further complaints until January 13, 1931, when he had some epigastric discomfort which he complained of until March 5, 1931, when it disappeared after which time he was symptom free for 10 weeks. X-ray series March 5, 1931, revealed a deformed stoma with a niche in the jejunum, distal to the site of the anastomosis which was exquisitely tender to palpation. Diagnosis: Jejunal ulcer. At this time the patient was receiving Saunderson's vaccine, intravenously and was returning weekly for treatment until May 31, 1931, when he had a return of his abdominal pain. Then he was given gastric mucin and on June 11, 1931, he was greatly improved and had very little discomfort. Two weeks later he was symptom free and was on an unrestricted diet. Since that time the patient has been practically symptom free, except for 3 flare-ups of symptoms lasting for 1 to 3 weeks. He was last seen January 24, 1934, at which time he was symptom free and had been so for approximately 1 year. X-ray series March 21, 1932, revealed the following: Folding of greater curvature of the stomach on either side of the stoma, with diminution of the normal jejunal marking in the distal loop of intestine but no niche or localized tenderness present. The evidence indicates a gastroduodenitis but the presence of an ulcer in association with it cannot be substantiated on the basis of the roentgenological evidence at this time.

This patient is of considerable interest as there seems to be very little question about the diagnosis of a gastrojejunal ulcer and with varying types of medical treatment this patient has been symptomatically cured for approximately 13½ years, and thus, of course, is important when one is usually taught that marginal ulcers do not respond to conservative treatment.

CASE 6 Male, Irish American, 36 years of age, admitted November 5, 1928, complaining of abdominal pain and having been discharged from the medical service of the hospital the day of admission to the clinic. Résumé of the hospital records was as follows: Admitted October 15, 1928, discharged November 5, 1928. Complaint: Pain in epigastrium coming on 1 to 2 hours after meals for the past 5 years, and it awakens him from his sleep. Occasionally he vomits but usually bicarbonate of soda, or food, relieves the pain. During the past year his pain has been getting more severe and more persistent and he has had very little freedom from his discomfort. X-ray series October 18, 1928, revealed a filling defect in the inner and outer part of the duodenum, characteristic of a duodenal ulcer. A Sippy diet was followed while he was in the hospital. The patient stated that 5 years before he was X-rayed and told he had a duodenal ulcer and was treated at that time for the ulcer with temporary improvement. He made only one visit to the clinic and was admitted to the hospital as an emergency case February 24, 1929, with a history of having been well since his discharge from the hospital until one week before his admission when he began having pain in his epigastrium. About 6 hours before his admission he felt a severe pain in his upper abdomen which caused him to collapse in the street, due to the intensity and was brought to the hospital in a taxi. A diagnosis of perforated duodenal ulcer was made, and the patient operated upon immediately. Operation revealed a duodenal ulcer in the anterior superior portion of the duodenum which had perforated. The indurated area was excised and the duodenum closed

with No. 1 chromic gut, 3 interrupted layers of sutures being used. An uneventful convalescence was made and the patient was discharged from the hospital March 15, 1929, and re-admitted to the clinic March 16, 1929. He was seen regularly in the clinic until August 10, 1929, and at the time of this visit he was complaining of pain in the epigastrium which he had for the past 2 weeks. Although he did not return to the clinic following this visit he was re-admitted to the hospital January 6, 1930, and discharged January 27, 1930. X-ray series January 8, 1930, revealed a persistent filling defect of the inner and outer borders of the duodenum with a 6 hour gastric residue of one-third of the meal. Operation on January 10, 1930, revealed the anterior superior portion of the duodenum an indurated area which had stippling over it and a partial obstruction of the pyloric ring, with slight dilatation of the stomach. A posterior gastro-enterostomy was done with No. 1 chromic sutures for the anastomosis, without clamps. The abdomen was closed in anatomical layers. The patient returned to the clinic February 1, 1930, at which time he was symptom free and his abdominal incision entirely healed, but he made only 3 visits and was last seen March 8, 1930, when he was perfectly well. He was not seen again until August 13, 1931, when he had no pain or complaints but returned March 3, 1933, complaining of severe abdominal pain for the past 3 days. X-ray series March 10, 1933, revealed tenderness over stoma, with a niche formation at the site of stoma. The patient was then put on a first week Sippy diet, with powders, and his symptoms improved. On May 4, 1933, he had gained 15 pounds and was free from complaints. On his last visit November 14, 1933, he was symptom free.

One can see that this patient was a rather unco-operative individual and no matter what the type of treatment was used on this patient a poor result could be expected, as he usually did not return for treatment until he had a return of symptoms, and he also used alcohol and tobacco to excess.

CASE 7 Male, Irish American, age 35 years, admitted to the clinic February 18, 1932, complaining of epigastric discomfort which was severe. He had been operated upon in 1924 for an ulcer of his stomach. Résumé of previous admissions was as follows: Patient admitted to Bellevue Hospital May 27, 1924, discharged June 15, 1924. Complaint: Attacks of pain in epigastrium since 1920 which would come on about 30 minutes to 3 hours after eating and was relieved by food. X-ray series May 29, 1929, revealed a duodenal ulcer but no 6 hour retention. Operation June 3, 1924. An ulcer on the anterior superior portion of the duodenum just distal to the pylorus which was penetrating through the entire coats of the duodenum but the gall bladder was normal. A posterior no-loop gastro-enterostomy was done without clamps, No. 1 chromic gut being used for the anastomosis. The ulcer was inverted by several interrupted mattress sutures and a routine appendectomy was done. At the time of entering the clinic February 18, 1932, the patient had been entirely well until 3 weeks before his admission when he began having epigastric pain which was more severe than that he had previously to his operation. X-rays on February 19, 1932, revealed an ulcer in the first portion of the duodenum but the patient was requested to return for a more careful study of the gastro-enterostomy stoma. Re-examination March 7, 1932, revealed a duodenal ulcer and a gastro-enterostomy functioning normally but no niche suggestive of an ulcer in this region was found. The patient's pain was so severe

that he was advised to enter the hospital for bed rest. He remained in the hospital for bed rest from March 8 to March 13. His symptoms subsided while in bed and on a Sippy diet and he asked to leave the hospital. He returned to the clinic for treatment and his pain became so severe within 2 weeks that he was forced to return to the hospital and was operated upon. In spite of negative X-ray findings a diagnosis of gastrojejunal ulcer was made and he was operated upon March 25, 1932. The abdomen was opened and the duodenum was found mobile but both palpation and inspection were negative for an ulcer. On inspecting the stomach from the previous gastro-enterostomy it was found to be patent and an ulcer was found on the posterior wall of the stomach near the anastomosis. The ulcer was about the size of a five cent piece, and penetrating from the posterior wall of the stomach into the pancreas. As it was not possible to dissociate the anastomosis and excise the ulcer, the only method of approach was a partial gastrectomy. The ulcer in the stomach was freed from the pancreas with difficulty and the jejunum at the site of the anastomosis was excised, and an end-to-end anastomosis done. An antibiotic anastomosis was done between the jejunum and stomach, using the proximal loop to the greater curvature, and distal to the lesser as it caused less rotation of the intestine by this approach, and No. 1 chromic sutures used. Then an entero-enterostomy was done between the proximal and distal loops of the jejunum.

The penetration of the ulcer into the pancreas necessitated a subtotal gastrectomy as the ulcer could not have been excised by any other surgical procedure. The patient made an uneventful convalescence following the operation and has been seen in the clinic at frequent intervals and was last seen November 15, 1933 at which time he was perfectly well and had no complaints. X-ray examination of the gastro-intestinal tract November 3, 1933 revealed the presence of a gastric resection but no evidence of a marginal ulcer.

It is worth while noting that this patient went for 7 years and 8 months entirely free from symptoms when his symptoms returned which were more severe than those for which he was operated upon. In spite of 2 negative X-ray series his pain was so excruciating that the diagnosis of gastrojejunal ulcer was made and the patient advised to have an operation. This patient illustrates that a marginal ulcer can occur at long intervals following gastro-enterostomy and that in spite of negative X-rays one can have such a complication.

CASE 5. Male, Irish American, 39 years of age, admitted to the clinic December 8, 1930, complaining of pain in the small of his back and epigastrium, with a history of having had stomach pain for the past 10 to 12 years. He had been operated upon in the Jewish Hospital, Brooklyn, only 6 months previous to admission for a perforated ulcer. Five years previous to that he had been operated upon in the Jersey City Hospital, an exploratory laparotomy and appendectomy having been done. X-ray series December 20, 1930, revealed a permanent deformity of the outer border of the first portion of the duodenum, characteristic of an ulcer with gastro-enterostomy stoma somewhat diminished, with only small amount of barium going through it. Report from the Jersey City Hospital stated

that the patient entered March 22, 1926, discharged April 27, 1926. X-ray series revealed irregular duodenum, other was negative, and he was operated upon April 7, an abdominal exploration revealing that the gall bladder, stomach and duodenum were normal, but an appendectomy was done. Patient was admitted to the Jewish Hospital, Brooklyn, March 14, 1930, discharged March 28, 1930. A few hours previous to admission he was seized with sudden pain in the epigastrium and taken to the hospital as an emergency case and operated upon the same day. At this time an old indurated pyloric ulcer was found which had perforated into the pancreas. Operation consisted of closure of the ulcer and a posterior gastro-enterostomy. The patient had relief from his discomfort for only a few weeks. For the past 4 months he has had persistent abdominal pain which is occasionally relieved by food. Saunderson's vaccine 0.2 cubic centimeters was given subcutaneously and this treatment was continued at weekly intervals. On January 15, 1931, he was on a fourth week Sippy diet and was feeling well and had no complaints. He failed to return regularly to the clinic, but on July 30, 1931, he had no complaints and had been symptom free since January. On August 13, the patient complained of severe pain in the epigastrium, and at this time he was advised to take gastric motus and a second week Sippy diet. Gastric motus caused nausea and vomiting and he discontinued it. An X-ray series on September 12, 1931, revealed a deformity of the duodenum characteristic of a duodenal ulcer with the gastro-enterostomy functioning normally. However he continued to have severe abdominal pain and in spite of a strict Sippy regimen and powders he obtained no relief. On October 22, 1931, he was still having severe pain but discontinued treatment and went to a private physician. He returned on September 9, 1932, still complaining of severe pain and was advised to enter the hospital for operation. X-ray series September 4, 1932, revealed a duodenal deformity, stoma normal, and no evidence of a marginal ulcer. Because of the severe pain and prolonged medical treatment however clinical diagnosis of gastrojejunal ulcer was made and operation advised. Operation September 9, 1932. When the abdomen was opened numerous adhesions were found and separated, also a large marginal ulcer on the jejunal side of the anastomosis which had perforated into the pancreas. Exploration of the pylorus failed to reveal any evidence of a duodenal lesion. The stoma was dissociated and the stomach was closed with 3 layers of interrupted No. 1 chromic gut. It was necessary to resect 8 inches of jejunum and to excise the ulcer from the pancreas, and an end-to-end anastomosis to the jejunum was done with No. 1 chromic gut, 3 layers of sutures being used. Patient made an uneventful convalescence and has been seen regularly in the clinic and was last seen November 12, 1933, when he had no pain or complaints referable to his abdomen.

This patient illustrates 3 interesting points. First, he had a duodenal ulcer and during an abdominal exploration the operating surgeon failed to find the lesion which is not an infrequent occurrence. Second, the patient had an acute perforated duodenal ulcer and a gastro-enterostomy was done which has been advocated in some clinics in acute perforations. In spite of this he developed a marginal ulcer immediately upon his discharge. Third, the X-ray series in this case were all negative, and the clinical diagnosis of jejunal ulcer was made in spite of the negative X-ray findings.

CASE 9 Male, Irish American, age 35 years, admitted to the clinic March 17 1932 complaining of abdominal pain. He had been operated upon twice for ulcers of his stomach. Patient states that he had had pain in the pit of his stomach since a small child which was relieved by food. It was considered hunger pain until the age of 16 when it became quite severe. He was treated for an ulcer from the age of 16 to 25 but the pain became gradually worse. X rays in 1918 revealed a duodenal ulcer and as the pain became gradually worse he was operated upon in the Brooklyn Hospital in 1925 and a gastro-enterostomy was done, following which he was free from symptoms for a period of 3 years when in 1928 the pain returned. In that year he was treated in the Kings County Hospital, Brooklyn, for 23 days on a milk diet and powders, following which he was symptom free for about 5 months. In April, 1930, his pain was severe and he went to the Mayo Clinic and was re-operated upon. The report from there revealed a perforating gastrojejunal ulcer with the major portion of the lesion being in the stomach, and perforating into the colon, with a duodenal ulcer on the posterior wall perforating into the pancreas. The operative procedure consisted of disconnecting the gastro-enterostomy, resecting the jejunum with an end-to-end anastomosis, and a resection of the stomach, one half of the stomach being removed and a Polya anastomosis being done. Following this operation the patient was free from symptoms until October 1930 when he had a recurrence of pain and since then he has continued to have recurrent attacks of epigastric pain. X-ray series February 18 1932 revealed a partial gastrectomy with a functioning stoma, without localized tenderness, or obstructive signs. The patient made only a visit to the clinic when on October 6 1932 he came in complaining of severe abdominal pain with a loss of 4 pounds in weight. X-ray series October 14, 1932 revealed a jejunal ulcer visualized fluoroscopically but the same was not seen on the plates. October 27 1932 patient complained of having had a hemorrhage, with tarry stools, and was in bed for 10 days. On November 3 the hemorrhage had stopped and he was feeling well. Since then the patient has continued to have attacks of pain every 4 to 6 weeks which may last for 1 to 3 weeks and are very severe. The patient follows a rather strict regimen with powders for the relief of pain. X-ray series April 17 1933 revealed the presence of a partial gastrectomy and a niche, with tenderness to palpation just distal to the site of anastomosis. Re-examination was requested in one month. The patient has not returned to the clinic since April 20, 1933.

This case is of interest as the patient had symptoms characteristic of an ulcer from early childhood and he was operated upon at the age of 25 and was symptom free for 3 years. He then developed recurrent symptoms and one year later was re-operated upon for a gastrojejunal ulcer. Following the gastric resection for the gastrojejunal ulcer the patient was well for 1½ years and then developed symptoms of a second jejunal ulcer. We have quite conclusive roentgenological proof that this patient is at the present time suffering from a second gastrojejunal ulcer following a gastric resection for the first marginal ulcer.

CASE 10 Male, Austrian Jew 54 years of age, admitted to the clinic December 11 1930, complaining of severe epigastric pain for 3 months. The patient had been operated upon in April, 1920 for an ulcer of his duodenum in Belle

vue Hospital and the records revealed a gastro-enterostomy was done. Following the operation he had been perfectly well and remained so until 1927 when he had a few symptoms but they cleared up immediately and until 3 months ago he had no real abdominal pain since his operation 10½ years previously. X-ray series November 26 1930 revealed an ulcer of the first portion of the duodenum and a normal gastro-enterostomy stoma. He was placed on a Sippy diet and his symptoms subsided within a few weeks. On January 27 1931 he was entirely symptom free and had been so for a period of 10 days. He was not seen between January and July 16 1931 when he returned complaining of pain in his epigastrium for 3 to 4 weeks. At this time he was placed on Saunderson's vaccine 10,000 intravenously which he received at weekly intervals, increasing the bacteria 10,000 per week. X-ray series August 11, 1931 showed a deformity of the first portion of the duodenum characteristic of a duodenal ulcer but there was no evidence of a marginal ulcer. From July until November the patient returned at weekly intervals and was following a strict Sippy diet in addition to Saunderson's vaccine which was given for 8 weeks without benefit, and then gastric mucin was given for 6 weeks without any relief. In view of his persistent pain he was advised to enter the hospital and was operated upon for a gastrojejunal ulcer. In spite of the negative X-ray series. He was admitted to the hospital November 11 1931 and was operated upon November 20, 1931. An ulcer was found on the posterior portion of the duodenum which was not adherent to the pancreas. In section of the posterior wall of the stomach revealed a large marginal ulcer with the transverse colon slightly adherent over the ulcer. The adhesions were freed but the walls had not been completely perforated. The defect was then closed. The anastomosis dissociated and the jejunum was closed in layers with No. 1 chromic gut, but it was not necessary to resect the jejunum. The stomach was also closed with No. 1 chromic gut. A chronic cholecystitis was found but there were no stones. Cholecystectomy was performed. In view of the poor condition of the patient it was thought inadvisable to do any further surgery on the stomach, although there was a definite ulcer in the duodenum. Since the operation the patient has returned regularly to the clinic and has been improved but continues to have epigastric distress. X-ray series October 17 1932 revealed an ulcer of the first portion of the duodenum but no 6 hour gastric retention. X-ray series August 4, 1933 revealed a deformity and tenderness over the duodenum but no obstruction or gastric residue. The patient was last seen October 5 1933 at which time he complained of epigastric distress and pain at intervals but the pains were much less severe than before his operation.

In this case the patient went symptom free for 10½ years after a gastro-enterostomy and then developed severe epigastric pain. In spite of 2 negative X-ray series and systematic medical regimen the symptoms persisted and the patient was operated upon for a marginal ulcer. The history of this case proves that a long follow up is necessary and too much reliance cannot be placed on X-ray findings.

CASE 11 Female, German, age 47 years, admitted to the clinic April 24, 1930, having been discharged from the hospital on April 1 1930. At the time of admission to the hospital February 14, 1930, she complained of pain in the right upper quadrant of 3 weeks' duration and for 2 weeks it has been getting more severe. She had been operated

This patient illustrates a gastrojejunal ulcer which occurred 6 years after a gastro-enterostomy which was performed for a true organic stenosis, following a plastic operation for a perforated duodenal ulcer. Both the first and second operations were done by one of us (J. W. H.). The patient was a most co-operative individual and in spite of the absolute indication for a gastro-enterostomy he developed a gastrojejunal ulcer which at the present time is under control with a dietary regimen.

SUMMARY

The cases here presented are reported in detail so as to give a complete clinical picture of each. Of 13 patients 5 were operated upon in hospitals in or around New York and 8 were operated upon at Bellevue Hospital; no 2 patients were operated upon by the same surgeon. From the review of our cases we feel that any conclusions drawn as to the percentage of gastrojejunal ulcers developing after gastro-enterostomy is most inaccurate unless the patient has been followed for a 10 year period, and also seen at frequent intervals with repeated X-ray examinations. A follow up letter in stomach cases we believe is not only inaccurate but misleading and instead of being a help usually presents false information. It is seen that 3 of our patients who came to operation developed symptoms of a marginal ulcer after 7 years, one 10½ years following gastro-enterostomy.

When one realizes that the great majority of our patients have been followed less than 5 years and that in 79 gastro-enterostomies we have encountered 13 gastrojejunal ulcers, or 16.4 per cent, and of the 13 cases 3 occurred after 7 years, it would seem that a 10 year follow up is necessary

in drawing conclusions as to the percentage of gastrojejunal ulcers.

It is important to emphasize that, to a great extent, gastrojejunal ulcers run the same course as do peptic ulcers, that is the patients have pain with periodicity and freedom from symptoms for intervals of weeks or months—one reason why the flare ups that are occasionally seen in patients after operation are passed over lightly if X-ray examinations have not been taken. Our cases have also illustrated that too much dependence cannot be placed upon a negative gastro-intestinal examination, for patients frequently will have a marginal ulcer in spite of several negative gastro-intestinal series.

Medical treatment should be tried for as long a period as the patient progresses satisfactorily because marginal ulcers will get symptomatic relief from conservative treatment the same as will any peptic ulcer. If the patient continues to have severe pain under medical treatment it usually means the marginal ulcer is perforating into some adjacent viscus—the pancreas and transverse colon being the organs most usually involved. For that reason it is best to submit a patient with a gastrojejunal ulcer suffering severe pain to a second operation rather than to continue medical treatment if the pain is not relieved or improved rather promptly under conservative treatment.

upon 5 years before admission in Germany for a gall-bladder disease and her impression was that the gall bladder had been removed at the time. X-ray series February 24, 1910, revealed the duodenum diminished in size but apparently normal, with a 6 hour residue of two-thirds of the motor meal. Operation February 5, 1910, revealed a normal gall bladder but in the second portion of the duodenum there was an area of induration on the posterior surface which was definitely adherent to the pancreas. A posterior gastro-entostomy was done, No. 2 chromic gut being used for the anastomosis. The patient developed a jejunal fistula which discharged for several weeks but the wound healed and the patient was discharged from the hospital April 1, 1910. She was symptom free following the operation and on September 5, 1910, X-ray series revealed the stomach normal but the duodenal bulb could not be visualized. On November 1 the patient complained of pain in the region of her scar and examination revealed a localized abscess in the incision. She was admitted to the hospital for incision and drainage of the abscess. While in the hospital she complained of cramping pain similar to that which she had previous to operation but more severe. On December 14, 1910, X-ray series revealed gastro-entostomy stoma functioning but a small niche formation at the site of stoma with tenderness over it, characteristic of a post-intestinal ulcer. The patient was discharged from the hospital January 5, 1911, and she returned to the clinic February 19, 1911 complaining of pain in back and upper abdomen. She continued to have abdominal pain although she was on fourth week Sippy diet and Sippy's stomach continuously beginning with 10,000 bacteria and increasing to the same quantity each week. October 1, 1911 the patient had a second abscess in the abdominal wall and was readmitted for incision and drainage of abscess. She remained in the hospital 4 days and since her discharge has not returned to the clinic for further treatment.

This patient developed a gastrointestinal ulcer within 6 months from the date of original operation.

CASE 2. Male, German American, age 47 years, was admitted to the clinic July 1, 1911 complaining of pain in upper abdomen. He has been operated upon for an ulcer of the stomach. Patient stated that following the operation he was well for 3 years and 6 months but since October of 1910 he has had abdominal discomfort similar to that he had previous to his operation but not so severe. In January of 1911 he was operated upon in the Wilford Hospital, Brooklyn, and at the time he was operated upon it was for a gall-bladder disease, an ulcer being discovered at the time of operation. Operation consisted of a posterior gastro-entostomy for duodenal ulcer, cholecystectomy and appendectomy. Following his operation the patient was entirely well for years and months after which period he began having cramping distress similar to that previous to his operation. X-ray series May 10, 1911 revealed gastro-entostomy stoma with a niche at the junction of the different loops of the jejunum and the duodenum slightly deformed with a gastric retention of one-fourth of the motor meal at the end of 6 hours. Diagnosis: Gastro-jejunal ulcer.

At the time of entering the clinic the patient was suffering from very severe abdominal pain and he was not on gastric suction which treatment he followed regularly. September 23, 1911 his weight was 155 pounds or gain of 10 pounds. Since May he has been entirely free of symptoms but X-ray series November 5, 1911, revealed the presence of a permanent duodenal deformity with the structure and function of the stomach normal. The patient has remain-

ed well since last period with very occasional flare-up of symptoms of 1 to 3 days duration about every 3 to 4 months. X-ray series March 14, 1912, revealed the structure and function of the stomach normal in 6 hour retention. X-ray series September 1, 1912, revealed no gastric residue at the end of 6 hours, deformity of bulb characteristic of a duodenal ulcer, and the jejunum and the site of anastomosis was markedly stenosed and deformed with a small speck of barium in the region of the stoma, due probably to a niche at the stoma. January 5, 1913, the patient was complaining of severe abdominal pain and again on January 10, but he did not return to the clinic. A barium follow-up on April 20, 1913, revealed that the patient had collapsed in the street and had been operated upon in the Wilford Hospital, Brooklyn, as an emergency case, presumably for a ruptured ulcer. Requests to that institution for a summary of their findings have not been answered.

This patient illustrates a marginal ulcer that unquestionably involved symptoms and X-ray evidence of healing although his symptoms returned and there was positive X-ray evidence that his marginal ulcer had returned. Presumably the ulcer performed necessitating an emergency operation. This case bears out a clinical observation that marginal ulcers will show periodicity the same as do any type of peptic ulcer whether it be gastric or duodenal.

CASE 3. Male, Scotch American, age 45 years of age, admitted to the clinic on January 14, 1912, with a history of having been operated upon in June, 1904, for a perforated duodenal ulcer. At that time a Hensley pyloroplasty was done and he was symptom free for about 2 years when he began to have distress after eating and was unable to eat large quantities without vomiting. Patient was re-operated upon October 14, 1907, for a peptic ulcerative stoma at the time of operation he had an aspirin stomia of the pylorus. A posterior gastro-entostomy was done with No. 2 chromic sutures for the anastomosis. A successful cure was made following the operation. At the time of his 2nd visit to the clinic in January 1912, he was symptom free and has been since his operation in October of 1912. The patient had had symptoms free 10 years previous to the perforation in 1904 and the pain before the resection came on about 3 years before death in June, 1912 to 2 months at a time, when it would disappear and he would feel perfectly comfortable for a period of 1 to 2 months. The patient remained in the clinic and remained regularly at monthly intervals through 1915 and 1916 and he was symptom free until August 20, 1916, when he complained of abdominal discomfort with occasional vomiting. Gastro-intestinal X-ray series done July 31, 1917, revealed the gastro-entostomy stoma normal in size, 6 hour retention. After a restricted diet he became symptom free in 2 weeks and remained well until September 10, 1917 when he complained of severe abdominal pain which he has had for 2 weeks.

The patient's pain was so severe that he was admitted to the hospital September 20, 1917, and remained until October 17, 1917. A gastro-intestinal series was done on October 6, and again on October 20, which revealed a niche in the jejunum just distal to the site of the anastomosis and a diagnosis of acute jejunal ulcer was made. The patient left the hospital symptom free on October 17, and has been seen in the clinic 4 or 5 times since and he has remained symptom free.

Fig. 1 Melano-epithelioma. Diffuse cellular growth and collections of melanin (Case 1)

Fig. 2 Melano-epithelioma. Alveolar formation also a few collections of melanin (Case 2)

She did this, and at that time there was no evidence of recurrence or extension of the process.

CASE 4. A housewife, aged 48 years, registered at the clinic January 1, 1932. Her chief complaints were of discomfort in the upper right abdominal quadrant and of a sinus at the lower end of the spine. The patient gave a very long and detailed history of attacks of abdominal discomfort, nausea, and vomiting aggravated by ingestion of fried or greasy foods, but denied having had jaundice at any time. The sinus mentioned had been present intermittently for 22 years.

The pulse rate, temperature, and blood pressure were normal. Laboratory examinations of the urine revealed a slight trace of albumin. Examination of the blood, including a platelet count, and estimation of the bleeding and coagulation time, did not disclose any variation from normal. Roentgenographic examination revealed that the heart was moderately enlarged, but there were no demonstrable lesions in the stomach or colon.

The heart sounds were distant, and the abdomen was scarred from previous surgical procedures which included

removal of an ovarian cyst from the left side in 1912, removal of a cyst from the right side in 1914, suspension of the uterus in 1914, an operation to relieve adhesions because of abdominal pain in 1915, and excision or section of "a nerve on the right side" for the relief of abdominal pain in 1916.

Sigmoidoscopic examination, limited to 20 centimeters because of the presence of sharp angulation, disclosed the presence of moderately extensive internal and external hemorrhoids and a draining sinus in the posterior median line, 3 centimeters from the anal edge. Operation was advised. The patient returned to her home and remained there until March, at which time she reappeared at the clinic for surgical attention. The fistula was repaired and the hemorrhoids were ligated and excised. The pathologist reported that the specimen removed was inflammatory cavernous hemangio-endotheliomatous tissue, with foreign body giant cells (Fig. 4).

Her convalescence was uneventful and there has been no evidence of recurrence of the condition up to the present time.

Fig. 3. Hemangio-endothelioma, graded 1. The endothelial cells to a large extent have differentiated into capillaries. (Case 3.)

Fig. 4. Hemangio-endothelioma graded 1. A cavernous area made up of erythrocytes and a papillary endothelial growth. (Case 4.)

Melano-epitheliomata are generally considered to be extremely malignant, giving rise to early and widespread metastases. Case 1 is typical. The original lesion was very small and apparently it was completely removed, but in spite of this the fatal outcome was comparatively rapid. The widespread metastasis was exemplified by the metastatic growths demonstrated in roentgenological examination of the thorax. Radium applied locally and over the groin did not cause appreciable retardation of the progress of the disease. In this case the gross appearance of the original tumor was not unlike that of a comparatively innocent but painful thrombotic external hemorrhoid. The fact that the intensity of the symptoms increased for 3 weeks instead of subsiding as is characteristic of the pain in cases of thrombotic external hemorrhoids, was sufficient to warn the examiner that the condition deserved added consideration and the spotty pigmentation in the skin suggested the possible underlying pathological condition.

Case 2 is more confusing, for the diagnosis was revealed only when the pathologist made his routine examination of the tissue removed at operation. The mass discovered was very small and the anal canal was scarred from previous treatment. The scar tissue so distorted the canal and the flexibility of the tissue in this region that the tumor could not be discovered by gross examination or palpation.

Hemangio-endotheliomata are relatively more rare than melano-epitheliomata, are less rapid in rate of growth and metastasis is less frequent. There is less information in the literature concerning these growths, but metastasis has been observed. MacCallum cited a case in which the original growth was in the small intestine and there were hundreds of metastatic growths in the liver. In another case the tumor arose in the region of the scapula of a boy. This tumor was partially resected, but it rapidly recurred and there was metastasis to the lungs. MacCallum stated that the tumor suggested a hypernephroma, but that no tumor was found in the kidneys, suprarenal glands, or elsewhere and that the metastatic growths were about the size of a pea. The same author mentioned Calmers who cited a case in which metastasis was to the internal organs.

Case 3 closely parallels Case 1. The duration of the growth was similar to that in Case 1 as was its anatomical situation. In Case 3 however the growth was painless, although increasing in size. Likewise it resembled a thrombotic external hemorrhoid, but the total absence of pain pointed to some other type of pathological process.

The fact that the patient had previously been informed that she had hemorrhoids, and the fact that she had an abnormally intense fear of cancer account for her close observation and prompt effort to seek a remedy for this condition.

To carry on the comparison of cases. Case 4 is very similar to Case 3 in that the neoplasm was discovered at the time of the routine examination of tissue by the pathologist.

These cases evoke consideration of several important phases in the diagnosis of anorectal lesions. It has been stated frequently that actual examination of the anus and rectum is more important than is the history obtained from patients relative to lesions of these parts. However the history cannot be totally ignored as is well illustrated by Cases 1 and 3. It is true that examination is of greater relative value than the history when considering anorectal lesions, but the history frequently will point out the salient differences in lesions that appear to be similar and it cannot be too lightly considered.

Two of the cases described prove the value of the routine macroscopic examination of tissue removed at operation. This routine is almost universal when large masses of tissue are removed or when a diagnosis is obscure but it is less rigidly maintained with regard to the comparatively small amounts of tissue removed during an anorectal operation. This is especially true when hemorrhoidectomy is performed.

The prognosis in cases of melano-epithelioma is grave, but it is not beyond reason to expect that if the growth could be discovered soon enough the prognosis could be altered favorably. It is worthy of note that McEuen has used roentgen therapy in six cases of melanosisarcoma and has reported two cures. In general, it is the feeling that these tumors are comparatively resistant to radium and roentgen therapy. Generally the outlook is much more optimistic for patients who are afflicted with hemangio-endotheliomata. These growths occur frequently in parts of the body where they attract attention rather early and surgical excision brings about cure in a large number of cases. The progress of the growth is slower and it is more responsive to the effects of radium and roentgen therapy.

It is interesting, but of little importance, that melano-epitheliomata in this group occurred in men and the hemangio-endotheliomata in women. A case of melanoma in a woman has just been reported by Marino. Kraker reported a case in which melanosisarcoma occurred so low in the rectum that the pathologist discovered epithelial cells of the squamous type on one border of the

tissue removed. Goldblatt also reported a case of melanoma in which the tumor projected from the rectum. The patients whose cases are here reported were within the so called cancer age but otherwise their ages were of no significance.

The differential diagnosis of anorectal lesions is not emphasized as frequently as is the differential diagnosis of pathological processes occurring in other parts of the body. These cases serve emphatically to point the need of considering the wide range of pathological possibilities in this region and also the close resemblance between the most benign and most malignant lesions.

RENAL TUBERCULOSIS AND NEPHROLITHIASIS AS ASSOCIATED DISEASES

DANIEL N EISENDRATH A B M D F A C S PARIS FRANCE

THE only available statistics as to the frequency of an association of renal tuberculosis and nephrolithiasis in a large number of cases are those of Brongersma, Wildbolz, Crenshaw of the Mayo Clinic, and Tardo.

Brongersma had never observed the combination in 1000 cases of renal tuberculosis. Wildbolz has seen the association in only 14 (1.4 per cent) of 1000 cases. In a recent paper "Calcification in Renal Tuberculosis" Crenshaw of the Mayo Clinic states that there was roentgenographic evidence of definite calcification in 131 or 7.1 per cent of 1817 cases. No distinction is made as to how many of the 131 cases represented simply calcification in the form of lime deposits in a tuberculous kidney and as to how many were cases of true, i.e. well formed, calculus formation found in association with renal tuberculosis. Braasch and Olson of the Mayo Clinic, in a paper published in 1919 stated that, in 19 of 1079 cases of renal tuberculosis, a true calculus formation was found. Tardo quoted by Gottstein collected 10 cases of calculus formation in 1047 cases of renal tuberculosis operated on in Italian clinics.

It is very important, as will be seen later under "General Considerations," to make a distinction between simple calcification and true stone formation in tuberculous kidneys from the standpoint of both diagnosis and of prognosis.

I have been able to find reports of 35 cases published since 1920 to which 5 personally observed cases are added. Although the total number of cases of an associated renal tuberculosis and

nephrolithiasis or ureterolithiasis is comparatively small the possible occurrence of such an association should be constantly borne in mind. In fact, Wildbolz goes so far as to say that one should suspect an associated renal tuberculosis in every case of renal or ureteral calculi associated with infection.

PERSONAL CASES

CASE 1. Clinical diagnosis renal tuberculosis, confirmed by operation. Small calculus in cavity of tuberculous kidney.

Patient was a female aged 39 years, who had had burning on urination and frequency for a year. She had an attack of renal colic 6 months before my first examination, which revealed evidences of right renal tuberculosis. Nephrectomy was performed and the specimen showed two small calculi in one of the cavities (Fig. 1) of a kidney which was the seat of a moderately advanced caseocavernous type of tuberculosis.

The diagnosis of renal tuberculosis was so apparent without roentgenographic evidence, that the latter seemed superfluous. Possibly the passage of a similar calculus had been the cause of the severe renal colic 6 months before. The calculi found at the time of operation were still attached to the wall of the cavity and had evidently been formed around a nucleus of necrotic material.

CASE 2. Clinical diagnosis calculous pyonephrosis. History of passage of calculi. Multiple shadows over right kidney region. Nephrectomy. Multiple soft, partly formed phosphatic calculi in cavities of tuberculous pyonephrosis.

A female, aged 38 years, had had frequent attacks of severe pain over the right kidney region associated with chills and fever. These attacks had been noted over a

Melano-epitheliomata are generally considered to be extremely malignant giving rise to early and widespread metastases. Case 1 is typical. The original lesion was very small, and apparently it was completely removed, but in spite of this the fatal outcome was comparatively rapid. The widespread metastases was exemplified by the metastatic growths demonstrated in roentgenological examination of the thorax. Radium applied locally and over the groin did not cause appreciable retardation of the progress of the disease. In this case the gross appearance of the original tumor was not unlike that of a comparatively innocent but painful thrombotic external hemorrhoid. The fact that the intensity of the symptoms increased for 3 weeks instead of subsiding as is characteristic of the pain in cases of thrombotic external hemorrhoids, was sufficient to warn the examiner that the condition deserved added consideration, and the "spotty pigmentation" in the skin suggested the possible underlying pathological condition.

Case 2 is more confusing for the diagnosis was revealed only when the pathologist made his routine examination of the tissue removed at operation. The mass discovered was very small, and the anal canal was scarred from previous treatment. The scar tissue so distorted the canal and the flexibility of the tissue in this region that the tumor could not be discovered by gross examination or palpation.

Hemangio-endotheliomata are relatively more rare than melano-epitheliomata are less rapid in rate of growth and metastasis is less frequent. There is less information in the literature concerning these growths, but metastasis has been observed. MacCallum cited a case in which the original growth was in the small intestine and there were hundreds of metastatic growths in the liver. In another case the tumor arose in the region of the scapula of a boy. This tumor was partially resected, but it rapidly recurred and there was metastasis to the lungs. MacCallum stated that the tumor suggested a hypernephroma but that no tumor was found in the kidneys, suprarenal glands, or elsewhere and that the metastatic growths were about the size of a pea. The same author mentioned Calmers, who cited a case in which metastasis was to the internal organs.

Case 3 closely parallels Case 1. The duration of the growth was similar to that in Case 1 as was its anatomical situation. In Case 3 however the growth was painless, although increasing in size. Likewise it resembled a thrombotic external hemorrhoid, but the total absence of pain pointed to some other type of pathological process.

The fact that the patient had previously been informed that she had hemorrhoids, and the fact that she had an abnormally intense fear of cancer account for her close observation and prompt effort to seek a remedy for this condition.

To carry on the comparison of cases Case 4 is very similar to Case 2 in that the neoplasm was discovered at the time of the routine examination of tissue by the pathologist.

These cases evoke consideration of several important phases in the diagnosis of anorectal lesions. It has been stated frequently that actual examination of the anus and rectum is more important than is the history obtained from patients relative to lesions of these parts. However the history cannot be totally ignored, as is well illustrated by Cases 1 and 3. It is true that examination is of greater relative value than the history when considering anorectal lesions, but the history frequently will point out the salient differences in lesions that appear to be similar and it cannot be too lightly considered.

Two of the cases described prove the value of the routine microscopic examination of tissue removed at operation. This routine is almost universal when large masses of tissue are removed or when a diagnosis is obscure but it is less rigidly maintained with regard to the comparatively small amounts of tissue removed during an anorectal operation. This is especially true when hemorrhoidectomy is performed.

The prognosis in cases of melano-epithelioma is grave but it is not beyond reason to expect that if the growth could be discovered soon enough, the prognosis could be altered favorably. It is worthy of note that McEwen has used roentgen therapy in six cases of melanocarcinoma and has reported two cures. In general, it is the feeling that these tumors are comparatively resistant to radium and roentgen therapy. Generally the outlook is much more optimistic for patients who are afflicted with hemangio-endotheliomata. These growths occur frequently in parts of the body where they attract attention rather early and surgical excision brings about cure in a large number of cases. The progress of the growth is slower and it is more responsive to the effects of radium and roentgen therapy.

It is interesting but of little importance that melano-epitheliomata in this group occurred in men and the hemangio-endotheliomata in women. A case of melanoma in a woman has just been reported by Marino. Kraker reported a case in which melanocarcinoma occurred so low in the rectum that the pathologist discovered epithelial cells of the squamous type on one border of the

tissue removed. Goldblatt also reported a case of melanoma in which the tumor projected from the rectum. The patients whose cases are here reported were within the so called cancer age but otherwise their ages were of no significance.

The differential diagnosis of anorectal lesions is not emphasized as frequently as is the differential diagnosis of pathological processes occurring in other parts of the body. These cases serve emphatically to point the need of considering the wide range of pathological possibilities in this region and also the close resemblance between the most benign and most malignant lesions.

RENAL TUBERCULOSIS AND NEPHROLITHIASIS AS ASSOCIATED DISEASES

DANIEL N. EISENDRATH, A. B. M. D. F. A. C. S. PARIS, FRANCE

THE only available statistics as to the frequency of an association of renal tuberculosis and nephrolithiasis in a large number of cases are those of Brongersma, Wildbolz, Crenshaw of the Mayo Clinic and Tardo.

Brongersma had never observed the combination in 1000 cases of renal tuberculosis. Wildbolz has seen the association in only 14 (1.4 per cent) of 1000 cases. In a recent paper, "Calcification in Renal Tuberculosis," Crenshaw of the Mayo Clinic states that there was roentgenographic evidence of definite calcification in 131, or 7.1 per cent of 1817 cases. No distinction is made as to how many of the 131 cases represented simply calcification in the form of lime deposits in a tuberculous kidney and as to how many were cases of true, i.e. well formed calculus formation found in association with renal tuberculosis. Braasch and Olson of the Mayo Clinic, in a paper published in 1919 stated that, in 19 of 1079 cases of renal tuberculosis a true calculus formation was found. Tardo quoted by Gottstein collected 10 cases of calculus formation in 1047 cases of renal tuberculosis operated on in Italian clinics.

It is very important, as will be seen later under "General Considerations" to make a distinction between simple calcification and true stone formation in tuberculous kidneys from the standpoint of both diagnosis and of prognosis.

I have been able to find reports of 35 cases published since 1920 to which 5 personally observed cases are added. Although the total number of cases of an associated renal tuberculosis and

nephrolithiasis or ureterolithiasis is comparatively small, the possible occurrence of such an association should be constantly borne in mind. In fact, Wildbolz goes so far as to say that one should suspect an associated renal tuberculosis in every case of renal or ureteral calculi associated with infection.

PERSONAL CASES

CASE 1. Clinical diagnosis renal tuberculosis, confirmed by operation. Small calculus in cavity of tuberculous kidney.

Patient was a female aged 39 years, who had had burning on urination and frequency for a year. She had an attack of renal colic 6 months before my first examination which revealed evidences of right renal tuberculosis. Nephrectomy was performed and the specimen showed two small calculi in one of the cavities (Fig. 1) of a kidney which was the seat of a moderately advanced caseocavemous type of tuberculosis.

The diagnosis of renal tuberculosis was so apparent without roentgenographic evidence, that the latter seemed superfluous. Possibly the passage of a similar calculus had been the cause of the severe renal colic 6 months before. The calculi found at the time of operation were still attached to the wall of the cavity and had evidently been formed around a nucleus of necrotic material.

CASE 2. Clinical diagnosis calcareous pyonephrosis. History of passage of calculi. Multiple shadows over right kidney region. Nephrectomy. Multiple soft, partly formed phosphatic calculi in cavities of tuberculous pyonephrosis.

A female, aged 38 years, had had frequent attacks of severe pain over the right kidney region, associated with chills and fever. These attacks had been noted over a

Fig. 2. Tuberculous kidney from Case 3. Note two small calculi lying in a cavity at lower pole. The arrow points toward the calculi. The severe renal colic in this case was probably due to the passage of a similar small calculus.

period of 5 years. The history revealed the passage of calculi. Multiple shadows of varying density (Fig. 2) and a palpable mass were noted over the right kidney region. The diagnosis (from these and other findings) was calcareous pyonephrosis. Nephrectomy was done. Examination of the specimen revealed an advanced stage of caseous tuberculous type of tuberculosis with almost every cavity filled by a soft calcareous material, which in places had assumed the form of a true calculus (Fig. 3).

The irregular contours and variation of density of the shadows (Fig. 2) so characteristic of calcified tuberculous lymph nodes and of calculi formed in tuberculous kidneys should have led us to suspect the latter condition with secondary calculus formation.

CASE 3. Clinical diagnosis: calcareous pyonephrosis. Mass and two shadows over right kidney. Marked pyuria. Previous operation for bladder stone. Nephrectomy. Coral calculus in pelvis and a smaller one in cavity of a tuberculous pyonephrosis.

A boy, 4 years old, had had a vesical calculus removed at age of 3 years. Two shadows (one branching and one smaller) were noted over the right kidney region (Fig. 4) and there was also a mass in the same region. Marked pyuria on right side was also noted. Nephrectomy for supposed non-tuberculous calcareous pyonephrosis was carried out. Examination of the specimen revealed a well formed, branching and a smaller round calculus, lying respectively in the pelvis and one of the cavities of a kidney which was the seat of an advanced tuberculosis (Fig. 5).

The history of an operation for vesical calculus and the presence of shadows which resembled, in

every respect, those found in nephrolithiasis, resulted in the erroneous diagnosis of non tuberculous infection.

CASE 4. Clinical diagnosis: infected stone kidney. Oval shadow and mass over the right kidney region. Operation revealed an oval calculus in the pelvis of the tuberculous kidney.

A female, aged 37 years, had recurrent pain over the right kidney and frequency of urination for past 3 years. Right ureteral rigid and gaping. Unable to catheterize right ureter. Crescentic shadows were present over the right kidney region (Fig. 6). The diagnosis made was renal calculus and non-tuberculous pyonephrosis. Examination of kidney after operation (nephrectomy) revealed a well formed, large calculus filling the pelvis of a kidney which was the seat of an advanced caseous form of tuberculosis (Fig. 7).

The appearance of the ureteral (right) orifice should have led to the suspicion that the concomitant infection was not of an ordinary pyogenic character.

CASE 5. Clinical diagnosis: Renal tuberculosis. Roentgenographic examination not made. At operation large coral calculus in pelvis of a tuberculous kidney.

A male, aged 45 years, gave a history of amputation of the limb for tuberculosis. A marked left pyuria was noted. Elimination of indogermine, absent. Many ulcers were noted around the left ureteral orifice. Siam was positive for tubercle bacilli in the urine from the left kidney. Hence nephrectomy for renal (left) tuberculosis. Examination of specimen revealed a large coral calculus in the renal pelvis of a kidney which was the seat of an advanced caseous form of tuberculosis. Some time later, operation was performed for tuberculosis of the epiphyseal.

This case shows the necessity of routine roentgenographic examination (plain film at least) in all cases of renal tuberculosis.

In none of these 5 cases was the correct diagnosis of an association of renal calculus and tuberculosis made. In Cases 3, 4, and 5, we believed the concomitant infection to be of a non-tuberculous character. This, as will be shown under "General Considerations," has been true of the majority of the reported cases. In Case 1, the calculus was probably too small to be recognized by roentgenography. In Case 5, such an examination was not considered necessary.

GENERAL CONSIDERATIONS

Types of calcification and calculus formation in tuberculosis of the kidney. In order to make a correct pre-operative diagnosis of the association of calculus formation and renal tuberculosis it is necessary to distinguish calcification in a tuberculous kidney and true calculus formation as shown in Cases 3, 4, and 5 just cited.

1. *Calcification in a tuberculous kidney.* This question has been very thoroughly studied by Brassch and Olson in 1919 and more recently

Fig. 2 Shadows of soft phosphatic calculi as found before operation in Case 2. Note the irregular contour and variation in density of the shadows.

(1930) by Crenshaw who makes the following division:

Group 1. Multiple scattered small areas, generally due to lime deposits. These are seen (a) as single, elongated, irregular faint streaks or (b) multiple punctate areas, scattered over a large portion of the kidney, usually in one of the poles.

Group 2. Single (Fig. 1) or several isolated areas of calcareous deposit which are easily confused with stone. These shadows are of several varieties:

a. Of irregular outline, with fainter shadow than that of stone and varying in size (as in Case 2, Fig. 2)

Fig. 4. Roentgenogram in Case 3. Note shadow of a branching calculus and of a smaller one. (Compare with Fig. 5.)

Fig. 3. Kidney from Case 2. Note the soft phosphatic calculi which fill and assume form of nearly every cavity and dilated calices.

b. Shadow of very irregular consistence and outline somewhat resembling filigree work.

c. Definite shadows with a density and contour suggestive of stone.

Group 3. Large, regular rounded shadows of variable density in their various portions. As a rule, the kidney is of putty like consistence in such areas. The shadow may vary in density in different portions of the kidney, some portions being so dim (Fig. 8) as to be scarcely discernible while in complete opacification the shadows may assume the outline of a complete cast (Fig. 9) of the kidney and are irregularly divided into lobules.

Fig. 5. Kidney from Case 3. Note the typical tuberculous pyonephrosis with a large calculus in the renal pelvis and a smaller one in a cavity.

FIG. 6. Roentgenogram from Case 4 showing irregular or crescentic shadow in right kidney region due to relatively large calculus (see Fig. 7).

2. *True calculus formation in a tuberculous kidney.* There is much difference of opinion in regard to which is primary, the tuberculosis or the calculus. If the latter is composed of oxalates or urates, it seems logical to believe that the calculus formation was independent of the tuberculosis. In the case of calculi composed of calcium carbonate and especially of calcium phosphate the secondary origin seems most probable. The

FIG. 7. Kidney from Case 4. Note the relatively large calculus in the pelvis of a kidney which is the seat of advanced tuberculous changes.

shadows due to true calculi do not differ in intensity or contour from those observed in non-tuberculous cases. This is well shown in Case 3 (Fig. 4). One can readily exclude the majority of extrarenal conditions such as calcified retroperitoneal lymph nodes by the use of the opaque catheter with or without pyelography. The shadows due to such nodes are as a rule characterized by an irregular moth-eaten contour and a variation in the intensity of the shadow. Occasionally these criteria cannot be depended on and ureteropyelography (retrograde) must be employed (Fig. 10).

FIG. 8. Moderately advanced degree of diffuse calcification in a tuberculous kidney. (Courtesy of Dr. J. L. Crenshaw and of the Mayo Clinic.)

FIG. 9. Very advanced degree of diffuse calcification in a tuberculous kidney. (Courtesy of Dr. J. L. Crenshaw and of the Mayo Clinic.)

Fig. 10. Roentgenogram from case in which the shadows of calcified retroperitoneal lymph nodes resembled those due to renal calculi. Note their change in position and their extra ureteral location as shown in ureteropyelogram.

Sermet has recently reported a case in which three calcified tuberculous nodes yielded shadows which were interpreted as calculi lying in the pelvis of a tuberculous kidney. At operation three calcified lymph nodes were found lying in close proximity to the renal pedicle.

One must also bear in mind that a true renal or ureteral (Fig. 11) calculus may be associated with a shadow due to a tuberculous lymph node.

Clinical groups. All of the cases thus far reported may be grouped as follows:

Group 1. Calculus and tuberculosis on the same side (Table I). Of the 40 cases (including my own 5 cases) reported since 1920, the majority—26 cases, belong in this group. They may be summarized as follows:

Pre-operative diagnosis (26 cases)

Renal or ureteral calculus with infection	13
Same and renal tuberculosis	1
Non-tuberculous pyonephrosis	2
Renal tuberculous only	9
Suspected renal tuberculosis	1
Suspected renal tuberculosis and calculus	1

Thus we see that in only one case (Case 6 of Group 1) was the correct diagnosis made before operation.

Roentgenographic evidence of calculi. Of the 19 cases, in which the results of the roentgenographic examination are given, only 3 yielded negative

Fig. 11. Simultaneous presence of ureteral calculus in the pelvic portion of the ureter and of a calcified lymph node. (Courtesy of Dr. Joseph S. Eisenstaedt.)

results. In 1 of my own cases (Fig. 2) the shadows were due to deposits of lime salts rather than to true calculi.

The same was true of one of Howald's cases.

Group 2. Tuberculosis on one calculus on the opposite side. The 5 cases in this group are of especial importance. At intervals varying from 26 days to 1 year after a nephrectomy for renal tuberculosis, an anuria due to an obstructing calculus in the ureter of the remaining kidney developed in the 5 cases of this group. In one of the cases (Grondahl) the roentgenographic examination was negative at the time the nephrectomy was performed. In the 4 others, there is no mention of such an examination.

Why calculus formation occurs in the remaining kidney following nephrectomy for tuberculosis is still being debated. Howald is of the

opinion that such calculus formation is favored by the forced feeding in sanatoria.

Group 3. Bilateral renal or ureteral calculi and unilateral tuberculosis (Table III). There were only 4 cases in this group. In Fowler's case, a nephrectomy was performed for the associated lesions. In Irisawa's case, a large coral calculus was removed from one kidney and a nephrectomy for the associated lesions performed on the other side. In one of Howald's cases nothing had been done, and in the other case, a nephrectomy.

**Group 4. Bilateral renal tuberculosis and uni-
lateral stone formation.** Only 5 cases belong in this group. Of interest are the cases of D Agata and of Kuzmickij. In the former a large calculus

was removed by nephrotomy from a tuberculous kidney. In Kuzmickij's case a calculous anuria developed 1 year after nephrectomy for renal tuberculosis. Autopsy revealed the presence of two calculi obstructing the ureter of the remaining tuberculous kidney.

Group 5. Bilateral renal tuberculosis and lukuria. Gottstein cites 4 cases (those of Helmut, Joseph Kuemmell and Liebermeister). They are of little practical clinical interest except from the standpoint of diagnosis.

TREATMENT OF THE VARIOUS GROUPS

Group 1. Tuberculosis and calculus on same side. It is generally accepted that nephrectomy

Nephrectomy. Death. Autopsy revealed two phlebotic calculi obstructing right ureter. Kidney (right) showed tuberculosis focus
Howard Loc. cit.	Bilateral renal tuberculosis and unilateral right nephrolithiasis	Positive. Large shadow over right kidney region			
Idem	Bilateral renal tuberculosis and unilateral right nephrolithiasis	No shadows	Removal of per-operative shadow (right) from which calculus was evacuated		
Idem J. Urol. 1926	Bilateral renal tuberculosis and nephrolithiasis	Positive multiple shadows	Nephrectomy for calculus in upper pole of tuberculosis kidney	Only caused anuria continued but showed tuberculosis in kidney	One kidney had been removed elsewhere for tuberculosis. Remained kidney showed calculus and tuberculosis

is the best method of treatment, at the present time, for a case of unilateral tuberculosis unless some contra-indication outside of the urinary tract, exists. The same indication exists when either calcification or true calculus formation is an associated condition.

If one has overlooked the existence of a renal tuberculosis in a case of unilateral renal or ureteral calculus, the following dangers may be present: (a) the persistence of a postoperative fistula; (b) the chances of recurrence of calculi are greatly increased.

Every case of renal or ureteral calculus associated with infection, should be examined for the possible co-existence of a renal tuberculosis. In the latter disease plain roentgenography at least, should precede nephrectomy in order to be

able to detect the presence of true calculus formation as an associated lesion. In such individuals the probability of calculus formation in the remaining kidney, at some future date, is probably greater than when renal tuberculosis exists alone.

Group 2. Tuberculosis on one side and calculus on the opposite side. If both conditions have been recognized at the first examination of the patient, Howard advises removal of the tuberculous kidney first and of the calculus at a later sitting. The writer believes the danger of a postoperative anuria is greatly lessened in the case of a ureteral calculus on the opposite side, by making every effort first to deliver the calculus by non-operative or operative means before the nephrectomy. The treatment of the calculous anuria which occurs

after operation, is the same as for that which occurs independently of a previous operation

Group 3 Bilateral calculi and unilateral tuberculosis In such cases, Howald advises removal of the kidney, which is the seat of the tuberculosis and calculus as a first step. In such cases, the writer would prefer to be guided by the same principles as in ordinary cases of bilateral renal (or ureteral) calculi viz to remove the calculi from the better side first

SUMMARY

1 The association of renal tuberculosis and of true calculus formation occurs in approximately 1.8 per cent of all cases of renal tuberculosis.

2 One must distinguish between calcification which is found in about 7 per cent of all cases of renal tuberculosis and true calculus formation.

3 Forty cases reported since 1920 the majority of which are instances of true calculus formation in tuberculous kidneys (on the same or opposite side) are tabulated. 5 of the 40 cases are personal observations of the author.

4. The cases can be placed in four clinical groups. The first and second of these are of especial importance. In the former if one overlooks

the concomitant tuberculosis in a case of renal or ureteral calculus, there is the danger of a persistent postoperative fistula as well as of early recurrence of calculi.

The only case in this first group (26 cases) in which a correct pre-operative diagnosis (of associated calculus and tuberculosis) was made is that of Adler Racz (Table I).

In the second group 5 cases reported since 1920 of calculous anuria following nephrectomy for tuberculosis at intervals of 26 days to 1 year, are cited. A number of similar cases were published prior to 1920 by Elliot, Kuemmel and others.

Plain roentgenography even in cases of well marked renal tuberculosis should be considered a routine measure in order to detect the presence of renal or ureteral calculi.

THE TREATMENT OF ACUTE SUPPURATIVE ARTHRITIS

REPORT OF THIRTY SIX CASES TREATED BY OPERATION

GEORGE A. L. INGE, M.D. F.A.C.S. NEW YORK

Fellow of New York Orthopaedic Dispensary and Hospital

FREDERICK L. LIEBOLT, M.D. NEW YORK

THE following study of the end results in the surgical treatment of acute suppurative arthritis is based upon 36 cases of this disease in which operations were performed at the New York Orthopaedic Hospital during the 15 years from 1918 to January 1, 1933. It will include only the cases in which movable joints were affected, thus excluding those in which the infection involved the sacroiliac joints where restoration of motion is not desired in the treatment. Also, because gonorrheal arthritis is a separate and distinct disease clinically and pathologically rarely proceeding to suppuration seldom if ever requiring incision no cases of this disease are included in the present study. Thus the report will deal only with acute non-specific purulent arthritis in movable joints.

HISTORICAL

The attitude of the medical profession toward this disease has been a singularly variable one. There has always been respect for it but the forms of treatment advocated for its cure have been many and these have often been diametrically opposed to each other in theory. Whether to incise or to aspirate, to mobilize or to immobilize, to disinfect or to irrigate, whether or not a drain should be inserted—these are questions about which there have been many differences of opinion.

In general it may be said that the chief concern of seventeenth and eighteenth century surgeons in such cases was to preserve the life of the patient; that the nineteenth century surgeon tried, in addition, to save the affected limb; and that with the beginning of the twentieth century came the idea of preserving the *function* of suppurative joints.

The attitude of the sixteenth century surgeons toward this disease is well expressed by Peter Lowe, who, in his *Discourse on the Whole Art of Chyrurgerie* (1597) writes of "The tumor or paine in the knees" as follows:

If it tend to suppuration beware to open it, for it is forbidden by our ancients to make deepe incisions under the rotule of the knee because those parts are both sensible

and painefull, and oftentimes with accidents ensue so you shall use corroborative remedies, and anodynes, evacuating the matter and cicatrizing the wound, as you have heard in others.

The seventeenth century surgeon Richard Wiseman, was the first to differentiate between acute suppuration in joints and a condition which he called "tumor albus," and which after Koch's time, was recognized as tuberculosis. The failure to distinguish between these two diseases, however, is apparent in the works of writers much later than Wiseman, and possibly accounts for much of the variation in the methods of treatment of purulent arthritis. Even today this differential diagnosis is not a simple one.

During the seventeenth and eighteenth centuries there was a passion for amputation of limbs, often with small provocation and pyarthrosis was not the least of the indications for removal of a limb. Joint suppuration was considered a serious threat to the patient's life and preservation of the limb was not considered feasible. Early in the nineteenth century a revolt against amputations was led by Sir William Ferguson, Astley Cooper, Brodie, and others, and it became the mode to try to save the limb as well as the life of the patient. The conception of the treatment of joint infections at this time is summarized by Sir Benjamin Brodie:

However formidable such cases of rapid suppuration and joint destruction may be they are now much under the control of art, so that the patient will in many instances recover preserving the limb, but not the motion of the joint, which remains immovable. If the joint be purulent, a free opening should be made in a depending situation. It is important that the operation be not long delayed, and that the opening should be sufficiently large to allow the matter to flow out spontaneously, but all this will be of little avail, unless the joint be kept in a state of most complete immobility.

The twentieth century ushers in a variety of new ideas in the treatment of this old disease. It suddenly becomes "criminal," according to one author (Cotton) or "an outrage" according to another (Reich) to treat an infected joint by the "ancient method" of drainage and the introduction of wicks: the one writer is sure that the proper

treatment is to close the joint tightly after incision and washing out of the pus, the other is just as sure that aspiration and lavage is the only treatment. Other authors in this period advocated 'disinfection' of the joint, and many were the kinds of chemicals recommended for this purpose. Chemical disinfection reached its zenith during the early years of the World War in the form of the Carrel Dakin irrigations.

The idea of preserving motion at the infected joint is relatively recent, and it is not yet by any means universally accepted. Even today there are surgeons whose attitude toward such joints is 'Let them ankylose in good position'. To whom the credit should go for first introducing the principle of maintaining function in purulent joints is not known but it was preached at the beginning of this century by Professor Erwin Payr of Leipzig.

In 1881 Macnamara described the use of drainage tubes in the incisions into purulent joints, drains however, were undoubtedly used long before this. Over no other question in the treatment of suppurative arthritis has there been so much controversy. Up to 1914 their use seems to have been general, but since then there has been widespread objection to the insertion of any foreign body into an infected joint. It is argued that drains will cause additional necrosis of tissues, especially of cartilage by pressure, or that they may cause thick walled sinuses, or the partitioning of the joint by firm adhesions. By the more vehement writers their use has been denounced as criminal by others as unnecessary. Dr Russell A. Hibbs, late chief surgeon of this hospital, always maintained that it was the pus which destroyed the tissues in such a joint that the obvious treatment was to evacuate this by the most effective possible means and that a properly used drain instead of damaging the joint, was the simplest and most efficient means of obtaining such a result.

During the World War, Willems, a Belgian army surgeon introduced a method for treating suppurating joints following penetrating wounds, which was hailed by many as revolutionary and as "the most valuable acquisition which the surgery of the war has given us (Cohn). The principles of this method were (a) wide arthrotomy, followed by (b) immediate, prolonged, full active motion and (c) walking on the affected limb as soon as the patient's temperature fell below 100 degrees F. Some observers reported that pus was actually squirted out of the wounds at each step when Willems patients walked. The treatment was calculated to cause thorough drainage of the pus

Fig. 1. Suppurative arthritis of right hip before operation. Marked effusion, no bone destruction. Duration of symptoms, 8 days. (Case 1 Table I)

by the active motion and weight bearing and it apparently was successful in some cases. The stoicism required of a patient in undergoing this method of treatment is, however, not common in peace time civil populations, as is shown in the case reports which have appeared in the literature. Willems himself, in his original report listed three ankyloses and one secondary resection in eleven purulent knees treated by his method, 36 per cent failures. This is somewhat better than the results obtained by other surgeons who have made case reports. For example, Depage and Delray had 42 per cent failures in 31 cases, Everidge had 60 per cent failures in 20 cases, Duval had 40 per cent failures in 5 cases, Cotte had 100 per cent failures in 8 cases, Cotton had 100 per cent failures in 2 cases.

Launay however, had 2 "successes" in 2 cases. No other case reports have been found in the literature. Desgouttes and Duguet, two contemporary French surgeons, report no cases of their own, but agree that the Willems treatment, unnecessary in mild cases, is impossible and contra-indicated in severe ones. The last named author advises resection for a purulent joint, and sums up the modern French attitude by saying "In these grave arthritides cure is only obtained by ankylosis, and it is exactly this which one obtains by resection. The functional point of view should not be considered." For "mild" cases he recommends arthrotomy and drainage, followed by immobilization and vaccine therapy.

Fig. 2. Same case as in Figure 1, 5 days after operation. Note rubber tube drain extending to capsule. The rubber dam drain which extends into the joint can be seen in the X-ray negative, but does not show up in the print.

Fig. 3. Same case as in Figures 1 and 2, 4 years after operation. Except for slight coxa magna and the small alarum deposit in the soft tissues, it is now a normal hip. No limitation of motion, no symptoms, a 4-4-4 result.

Fig. 4. Suppurative arthritis of right hip, complicated by osteomyelitis of femoral neck and head, duration of symptoms 49 days before coming to hospital. (Case 31, Table I.)

Fig. 5. Same case as in Figure 4, 3 1/2 years after arthrodesis and drainage showing mediocre result which is due to previous bone destruction. A 3-4-3 result was obtained.

The Willems treatment has met varied reception in this country. In some medical schools it is taught exclusively. However, Caldwell, among others, has decried its use, and in 1925 Blake laid down much more conservative principles for the treatment of pyogenic joints. The latter author likened suppurative arthritis to suppurative peritonitis and suppurative pleurisy, and stated:

"In both instances, if opened and drained in the early stages, the outcome is often bad, but if treated by the closed method (i.e., repeated aspiration) the results are far better. Aspiration should be repeated until resolution occurs or one becomes convinced that the destruction of tissue, such as cartilage, has taken place, when incision and drainage become necessary." Blake states that this method is particularly applicable to streptococcus infections, and rarely, if ever, to those in which the staphylococcus is involved. He makes no case reports. At the present time most surgeons would probably agree that what ever may be the possibilities of aspiration in streptococcus infection, a joint with pus in it should have an early diagnosis and early arthrotomy. Destruction of cartilage should thus be obviated rather than waited for.

Chemical disinfection following arthrotomy still has its adherents and mercuric chloride (Cotton), ether (Duguet), Dakin's solution (Cotton), and Chlumsky's solution (Kortzeborn) have been advocated for this purpose within fairly recent times. Several French authors (Lapointe and Bazy, Mirailhé, Thiféry, Wiart) have reported 'cures' of suppurating joints by the injection of bacteriophage without arthrotomy. One of these claims the singular good fortune of "curing" a streptococcus suppurative arthritis by injecting a *staphylococcus* bacteriophage into the joint. Such results have not been substantiated by others.

Most of the literature on acute suppurative arthritis is worthless because of the prevalence of opinions based upon theory, and the surprising meagerness of accurate, detailed case reports. Even when cases are reported, the so called "successes or cures" or "perfect results" are often meaningless because these terms are not defined by the author. A knee joint with 10 degrees of motion left in it may be a "success" to one surgeon but by another it would be considered a poor result. The important question of the bacteriology of the cases is rarely discussed, unless it is to say that some were due to the gonococcus, which fact alone should be enough to eliminate such cases from a study of suppurative arthritis.

A series of cases reported by Kortzeborn and Hesse, in 1931, from the Leipzig clinic, con-

stitutes the largest and most completely worked up series found in the literature. These authors prefer to treat a purulent joint by aspiration, injection of Chlumsky's solution, and early motion, although their results in 19 joints so treated were good function in 4 or 21 per cent, fair function in 4, ankylosis in 5 or 26 per cent, and death in 5 (26 per cent). Cause of death was sepsis in 2 cases, pyæmia in 1, marasmus in 2.

Fourteen of their cases were comparable to those we are about to report, i.e., cases complicated by penetrating wounds or bone injury, treated by arthrotomy and drainage. Their results were unbelievably bad, there being in 14 cases, 1 death, 1 amputation, 8 bony and 2 fibrous ankyloses, only 2 cases retained partial function. These authors are thus forced to the dismal conclusion that "in all joint suppurations which necessitate a wide opening, one must give up all thought of preserving function." They refrain from using the Willems method because of its inhumanity and the impossibility of carrying it out. The knee was the joint most frequently involved, the staphylococcus the most frequent causative organism. This bacterium was responsible for 7 of their 11 deaths, but the greater percentage of ankyloses occurred with the streptococcus. 45 per cent of the streptococcus cases showed ankylosis, whereas only 25 per cent of the staphylococcus cases in which death did not occur showed this result.

PROBLEMS OF TREATMENT

After a study of the literature on the subject one therefore is left in a dilemma regarding four major problems in the treatment of acute suppurative arthritis:

- 1 Should a purulent joint be promptly incised, or should it be repeatedly aspirated until cured?
- 2 Should a joint which has been incised have a drain inserted, to ensure the maintenance of an issue for the exudate?
- 3 Does complete rest and immobilization offer a better chance for restoration of function than immediate, forced, and prolonged active motion?
- 4 Does lavage with chemical or biological products offer any hope in the treatment of a purulent joint, with or without incision?

It is hoped that the results obtained in the following series of cases will help to answer these problems.

REPORT OF CASES

In the past fifteen years operations have been performed in this hospital in 36 cases of acute suppurative arthritis.

TABLE I
Group One

No. and Age	Sex	Time of admission to hospital	Temperature	White blood cells	Operation, type of drainage	Culture	Menses began	Drain removed	Length of follow up	End Results
										Anatomical By symptoms Functional
1. M 3 yrs	Male	May 10 9	101° T 101° W B C 14,000 54%		Posterior drainage. Rubber tube drain entered in Truncus. Tip in chest. Craniotomy.	Staphylococcus aureus.	Periods in 1st, active later.	6th day yes		No pain, stiffness, fatigue. No other symptoms. No further changes in symptoms. Widespread infection in all directions in external region to 4.
2. G 3 yrs	Female	May 10 10	101° T 101° W B C 6,900 54%		Posterior drainage. Rubber tube drain entered in Truncus. Tip in chest. Craniotomy.	Staphylococcus aureus.	Periods in 1st, active later.	6th day yes		No pain, stiffness, fatigue. No other symptoms. No further changes in symptoms. Widespread infection in all directions in external region to 4.
3. A 3 yrs	Female	May 10 11	101° T 101° W B C 6,900 54%		Posterior drainage. Rubber tube drain entered in Truncus. Tip in chest. Craniotomy.	Staphylococcus aureus.	Periods in 1st, active later.	6th day yes		No pain, stiffness, fatigue. No other symptoms. No further changes in symptoms. Widespread infection in all directions in external region to 4.
4. A 3 yrs	Female	May 10 12	101° T 101° W B C 6,900 54%		Posterior drainage. Rubber tube drain entered in Truncus. Tip in chest. Craniotomy.	Staphylococcus aureus.	Periods in 1st, active later.	6th day yes		No pain, stiffness, fatigue. No other symptoms. No further changes in symptoms. Widespread infection in all directions in external region to 4.
5. O 3 yrs	Female	May 10 13	101° T 101° W B C 6,900 54%		Posterior drainage. Rubber tube drain entered in Truncus. Tip in chest. Craniotomy.	Staphylococcus aureus.	Periods in 1st, active later.	6th day yes		No pain, stiffness, fatigue. No other symptoms. No further changes in symptoms. Widespread infection in all directions in external region to 4.
6. W 3 yrs	Female	May 10 14	101° T 101° W B C 6,900 54%		Posterior drainage. Rubber tube drain entered in Truncus. Tip in chest. Craniotomy.	Staphylococcus aureus.	Periods in 1st, active later.	6th day yes		No pain, stiffness, fatigue. No other symptoms. No further changes in symptoms. Widespread infection in all directions in external region to 4.
7. A 3 yrs	Female	May 10 15	101° T 101° W B C 6,900 54%		Posterior drainage. Rubber tube drain entered in Truncus. Tip in chest. Craniotomy.	Staphylococcus aureus.	Periods in 1st, active later.	6th day yes		No pain, stiffness, fatigue. No other symptoms. No further changes in symptoms. Widespread infection in all directions in external region to 4.

Grayish yellow pus	None	Non-hemo- lytic strep- tococcus 2 1/2 yrs	Hip still debilitated when last seen	N pain, no drainage Walks with a hip splint	Hip still debilitated Subluxation opera- tion advised

In order to clarify the study, the cases have been divided into three groups, as follows

Group 1 consists of 22 cases which were bacteriologically proved and which were not complicated by bone infection. This group constitutes the main series upon which this study is based.

Group 2 consists of 4 cases similar in every way to the above except that they were not bacteriologically proved.

Group 3 consists of 10 cases, all proved bacteriologically but which were complicated by osteomyelitis at the joint.

Group 1

Twenty two cases, bacteriologically proved uncomplicated

Incidence There were 5 females and 17 males, a ratio of 1 to 3.4. Age at operation ranged from 6 months to 14 years (except for one male of 32), averaging 6.5 years. The disease is thus essentially one of childhood

The hip was affected in 10 cases, or 45.5 per cent the knee in 6 or 27 per cent. There were 3 elbows, 2 ankles, and 1 shoulder

Etiology With one exception (Case 11 Table I), all the infections in this group were of metastatic hematogenous origin. The etiology of such infections can rarely be definitely established. A history of definite trauma was obtained from 5 patients and in 15 or 68 per cent of the group there was evidence of foci of infection which might have had a causal relationship. Only two patients had neither focus of infection nor trauma. The foci of infection encountered, in the order of their frequency were infected tonsils, chronic osteomyelitis in a distant bone (i.e. a bone not entering into the formation of the affected joint) otitis media pyelitis septicæmia purulent cervical adenitis, pneumonia.

Symptoms and physical signs did not differ, in this series, from the usual textbook descriptions. The most constant symptoms were pain and inability to use the affected joint, with swelling in all cases except some of those in which the hip was affected. Varying degrees of general reaction were present, from high fever and prostration to moderate pyrexia and malaise. The duration of symptoms before operation varied between 2 and 28 days averaging 9 days. Often the patient had been treated at home during these important days without a correct diagnosis.

The temperature per rectum ranged from 99.4 to 105 degrees F., the mean temperature on admission being 102 degrees. The white blood cell count was listed as low as 6,800 and as high as 52,800 with a mean of 16,800. The mean per

centage of polymorphonuclear leucocytes was 72.0 per cent.

Roentgenograms strongly suggested pyarthrosis in 9 cases, in 7 cases the evidence from this source was less helpful, while 6 patients had no pre-operative roentgenogram

Diagnosis This is more difficult than one is led to believe. Especially is there difficulty in the differential diagnosis between this condition and (a) joint tuberculosis, (b) acute rheumatic fever, (c) sympathetic sterile effusion into a joint near infected area, as osteomyelitis or cellulitis, (d) acute non-suppurative infectious synovitis.

There is no single test for joint suppuration. The history, physical examination, clinical laboratory reports, and roentgenograms must all be carefully studied, and observation in the hospital for a day or two may be necessary to arrive at a diagnosis. It is probably less serious to open a sterile joint than to fail to open a purulent one although in the presence of surrounding inflammation the most acute surgical judgment is needed to make such a decision. *Aspiration* of the exudate for the purpose of diagnosis is invaluable. This should be performed in every case in which there is any doubt about the diagnosis, smears and cultures being made immediately, even if both of these are negative however arthrotomy should be performed if the clinical and roentgenographic signs are sufficiently suggestive of suppuration

The positive diagnosis of pyarthrosis cannot be made in the early stages from the roentgenogram alone, but when an effusion, the density of which is consistent with pus, is seen in a joint having the necessary history and physical signs, that diagnosis is strongly suggested.

Operation In 20 patients of Group 1 the purulent joint was treated by wide arthrotomy, and a drain was placed into the joint cavity in each case to ensure continued evacuation of the pus. The material used for these intracapsular drains was soft rubber dam or soft goiter tubing heavy walled rubber tubes were placed down to capsule when necessary to preserve a drainage tract through thick muscle layers as at the hip. All drains were usually sutured in place. At the knee, the rubber dam drain was often placed completely through the joint, traversing the suprapatellar pouch

Incisions were placed in dependent situations when the anatomy of the joint made this feasible e.g. posteriorly at the hip (except in 2 cases) and shoulder, posterolaterally at the elbow at the knee two longitudinal incisions were made, one on each side of the patella.

In the 2 remaining joints of Group 1 arthrotomy was not performed for the reason that the diagnostic aspiration of pus was followed by rapid unexpected, and complete resolution of the infection. They were undoubtedly infections with attenuated organisms, one an elbow from which *Staphylococcus aureus* was cultured, the other a pneumococcal infection of the knee (Cases 19 and 22). The diagnostic paracentesis had no such effect in the remaining cases.

Pathology. Every joint in this series was a definitely purulent one when opened. In all cases pus was encountered varying in consistency from thin gray seropurulent exudate to thick, yellow creamy pus. The synovial membrane was usually severely injected and hypertrophied, with more or less necrosis; the capsule and peri-articular structures were usually described as edematous. Granulation tissue in many instances encroached upon the articular cartilage, but in every case in this group in which the operative note described it, the cartilage itself was said to be intact.

In no case in Group 1 was there any destruction of bone, either before the arthrotomy or subsequent to it. Nor was there any case of phlegmon extending from the joint through the fascial planes of the extremity.

Microscopic sections were made in only 6 cases. It has been the feeling in this hospital that the arthrotomy in a purulent joint should be done as quickly as possible with no unnecessary opening up of new tissue spaces to the infection. Hence the paucity of material for microscopic study. The sections which were made confirm the already well known pathological picture: a synovial membrane thickened by edema, hypertrophy and hyperplasia, these processes extending also into the subsynovial areolar tissues to varying extents; synovial membrane and underlying tissue densely infiltrated with polymorphonuclear leucocytes, and more or less extensive necrosis of the superficial layers of synovial membrane.

Bacteriology. Positive cultures were obtained from all the joints in Group 1. The organisms encountered in the order of their frequency were

	Cases	Per cent
<i>Staphylococcus aureus</i>	7	32
Hemolytic streptococcus	4	18
Non-hemolytic streptococcus	3	14
<i>Staphylococcus plus streptococcus</i>	3	14
Pneumococcus	3	14
* <i>Staphylococcus</i> (anxiety not stated)		4.5
<i>Bacillus pyocyaneus</i>	1	4.5

The *Bacillus pyocyaneus* is not common in this disease. In this case an operation on the prepa-

tellar region performed at another hospital, resulted in a *Bacillus pyocyaneus* infection, and the patient was brought to us after the knee became involved (Case 11).

The virulence of these organisms and the results obtained in joints infected with each, will be discussed presently.

Complications. The complications usually spoken of in treatises on acute suppurative arthritis are septicæmia, osteomyelitis, phlegmon, ankylosis, amputation death. None of these untoward events occurred in any case in Groups 1 and 2 of this series. One patient (Case 21) with a purulent shoulder had several recurrences requiring arthrotomy; another had a pathological dislocation of the hip. There were no other serious complications.

Postoperative treatment. Motion. Gentle passive motion was instituted immediately after the operation and this was replaced by active motion as quickly as the patient was able to bear it. The average time at which active motion was begun was 2.5 days after operation, although records of this were not kept on all of the charts. In 2 cases (12 and 14) the arthrotomized knee had to be moved under anesthesia at 6 weeks and 12 days, respectively because of stiffness. Both of these patients obtained good, but not excellent, results.

Removal of drains depended upon the decrease in drainage and the patient's temperature. The rule was gradually to withdraw the drain as fast as the subsidence of the infection would allow. Complete removal usually occurred between the seventh and twenty first days, though it varied between the first and the fortieth days after operation. Dakin irrigations were used in 1 case.

Traction was used in 10 of the 18 cases of lower extremity involvement. 8 hips and 2 knees were thus treated. No figures were available as to how long the traction was maintained.

Weight-bearing was not forced. The earliest day on which walking was begun in a lower extremity case was the twenty-eighth day after operation and the average was 45 days. The date was determined by the general condition of the patient and the appearance of the joint.

Results of the operations. All but 9 of the patients were seen and examined by the authors in the follow up clinic, and their condition at the time determined as accurately as possible. When it was impossible to get a patient in for examination, his condition was estimated from the most recent notes on his history.

The length of time elapsed between operation and final follow up examination for this group averaged 4.3 years, there being only 1 case with a

follow up of less than 1 year and the longest period below 14 years.

The result of the treatment in each case was evaluated according to the anatomical symptomatic and functional condition of the joint at the time of last examination, the degree of success obtained by the operation was indicated numerically from 0 to 4 in each of the named categories of anatomy symptoms, and function 0, representing a failure, 1, a poor result 2, fair 3 good, and 4 an excellent result. This system of follow up evaluation was originated at the Presbyterian Hospital in New York City in 1914, and was described in *The Medical and Surgical Reports* of that institution in 1918 by Dr James A. Corscaden. According to this system an excellent result is designated an anatomical 4, symptomatic 4, functional 4, or more simply as 4-4-4, a complete failure would be 0-0-0. A patient who had a good anatomical excellent symptomatic but poor functional result would be classed 3-4-1.

In estimating the anatomical result of the operations, account was taken of such variations from the normal as shortening atrophy bone destruction, relaxation subluxation, dislocation, flexion deformity, and ankylosis. For the symptomatic result, the patient's complaints of pain, stiffness, limp, and fatigue were weighed. To determine the functional or economic result a careful study was made of the exact range of motion at the joint, these measurements being made personally by the authors in most of the cases, also the gait the handicap in work or athletics, the ability to execute skilled movements were studied.

The personal judgment of the authors was necessarily called into play in arriving at the numerical classification of these cases, particularly of those not examined personally in the follow up clinic. If there was any difficulty in estimating any phase of a result, the classification was purposely made to err toward the lower rating. If ankylosis occurred in any joint it was considered an anatomical as well as a functional failure. Table I gives a short résumé of every case in the series, with its anatomical, symptomatic and functional result and the numerical classification.

Of the 22 patients in Group 1 there were 12 or 54 per cent in whom the anatomical symptomatic and functional results were all excellent, i.e., 4-4-4 results or joints restored practically to normal. These patients have little if any residual of the disease apparent in the roentgenogram no pain stiffness, or limp and no limitation of motion or activity.

In addition to these 12 excellent results, there were 5, or 23 per cent, in whom good results were obtained, viz. one 3-4-4, two 3-4-3's, one 3-3-3, one 2-4-4. One result was fair, a 3-4-2, and 2, or 9 per cent of the group, were listed as poor, one of the latter was a 0-0-0 because of a pathological dislocation which the patient refused to have treated (Case 5), and the other was a 3-0-0 a patient with numerous recurrences, who finally disappeared, still in need of another operation (Case 21).

Two patients in this group could not be classified because of insufficient data.

The average duration of symptoms before operation in the excellent results was 7 5 days, the majority being less than 5 days for the good and fair results the average was 12 days. The one poor result in which the duration was certain had had symptoms for only 3 days.

The postoperative temperature reached normal in from 4 to 33 days averaging 15. The average time required for the healing of the wounds was 48 days.

Group 2

Four cases, not proved bacteriologically, un complicated.

These cases differ from those in Group 1 in no way except that the causative bacterium was not determined. In 3 cultures were taken at the time of arthrotomy and no growth occurred in the other, there is no record of a culture having reached the laboratory. Clinically and pathologically they were typical cases of acute suppurative arthritis without involvement of the bone.

The mean temperature and blood count, and the operative procedure were approximately the same as in the previous group. Drains were used in each case and in each joint pus was found. The follow up averaged 7 7 years, ranging between 5 and 11 years. Two hips and two knees were involved.

The outcome in these cases was 4-4-4 in 2, 0-4-0 in 1, and 1-0-1 in 1, or, two excellent and two poor results.

Group 3

Ten cases bacteriologically proved, with bone involvement.

The hip was the joint affected in every case in this group. The bone infection was an acute osteomyelitis of the femur or acetabulum or both present at the time of admission to the hospital, in no case was there a focus of chronic osteomyelitis in another bone.

TABLE II.—END-RESULTS ACCORDING TO GROUPS

End Result	Group 1	Group 2	Group 3
4-4-4	18	3

0-3-0			1
3-0-0			
0-2-0			1
Unclassifiable	1	1	
Total No of Cases	22	4	10

The average age of this group was 57 years, and the average duration of symptoms before operation was 49 days (in Group 1 it was 9 days) exclusive of one patient who had been treated in another hospital in a spica, without operation, for 200 days.

Symptoms, physical signs, temperature, and blood counts did not differ materially from the cases in Group 1.

The causative organisms were staphylococcus in 4 cases, streptococcus in 4, mixed staphylococcus and streptococcus in 1 and mixed streptococcus and *Bacillus coli* in 1.

The arthrotomy and insertion of drain in this group had to be followed in all but 2 cases by subsequent operations for the removal of sequestra, partial osteotomy or to widen the drainage tract. Hence the pathology and the postoperative course were somewhat different from the cases in Group 1. It was impossible to say whether the osteomyelitis or the arthritis was the original lesion in these cases; there is little doubt, however, that an undiagnosed, untreated pyarthrosis at the hip could be expected to cause bone infection sooner or later.

Traction was used in 6 of these cases and a plaster spica in 1. Attempts to establish motion met with much less success than in the uncomplicated cases. The removal of drains, healing of sinuses, and length of stay in bed were determined by the progress of the osteomyelitis rather than by the joint infection.

The follow-up period for this group averaged 7 years. Among the 10 cases there were no excellent results, although 6 patients were completely relieved of symptoms. 4 results may be called good (Cases 30, 31, 32, 34) 1 poor (Case 28) while 5 were failures. Four of the failures were due to ankylosis, 1 to an irreducible dislocation which was present on admission. There were no deaths,

amputations, or cases of septicemia; the one phlegmonous abscess was present on admission in the patient (Case 33) who had lain 200 days in a spica in another hospital, and was undoubtedly due to the long delayed operation.

Thus 50 per cent of the cases in this group resulted in failures with no excellent results. When the outcome of these cases is compared with that of the cases in Group 1, it is seen that the presence of bone infection as a complication of purulent arthritis greatly increases the seriousness of the disease, and renders the prognosis for function much less sanguine. Table II shows graphically the results in each group.

FACTORS INFLUENCING FINAL RESULTS

The results of the treatment in this series of cases are surprisingly good when compared with the case reports in the literature. The factors which may have some bearing on this difference will be discussed under the following headings:

1. *Virulence of the infection.* There were of course, wide variations in the virulence of the infecting bacteria, as is shown by the fact that one patient with a *Staphylococcus aureus* infection of the knee recovered after simple aspiration, whereas others with the same organism were prostrated with a very severe infection and ended with poor joints in spite of early and efficient treatment. Low virulence of the bacteria may account for some of the excellent results obtained in this series, but that it cannot account for all of them will be evident to one who studies the figures for temperature and blood counts given in Table I. It may not be unusual to see a joint infected with the pneumococcus get well with aspiration, but this must certainly be an unusual event with the staphylococcus. The authors can not speak with experience about the result of aspiration as the sole method of treating streptococcus pyarthroses. Table III shows the end-results of the cases in Group 1 arranged according to the infecting organism.

2. *Early diagnosis and arthrotomy.* There was little temporizing with purulent joints in this series. Arthrotomy was performed in each case as soon as was feasible after the diagnosis was made. The only delay was in the patient getting to the hospital. The best results, in general, were obtained in those joints which had early diagnosis and early arthrotomy.

3. *The use of drains.* Far from constituting a misdemeanor it is believed that the results in this series of cases will show that the use of soft rubber drains into the joint cavity is one of the most helpful adjuncts in the treatment of pyogenic joints.

TABLE III—END-RESULTS IN GROUP I ACCORDING TO INFECTING ORGANISM

Result	4-4-4	3-4-4	3-4-3	3-4-2	3-3-3	2-4-4	3-0-0	0-4-0	Unclassifiable	Total No of cases

3-4-4									1											1					
3-4-3														1											
3-4-2			1																						
3-3-3																									1
2-4-4														1											
3-0-0		1																							
Unknown			1																						

In one case, the duration of symptoms was unknown

The drains must be soft, they must not be large enough to cause pressure necrosis and they should be withdrawn as rapidly after operation as the subsiding of the infection will permit.

4. *Traction* It is believed that the routine use of traction in these cases has exerted a favorable influence. Traction helps to relieve pain to prevent or overcome flexion deformities, and possibly to protect the articular cartilages if as Phemister claimed, necrosis of this tissue first occurs at points of pressure in a suppurating joint. The traction apparatus must be so applied that it will not interfere with free motion at the joint. The simplest method is by means of an anklet and a weight over a pulley at the end of the bed.

5. *Motion* A great deal has been written in the literature about active versus passive motion, much to the discredit of the latter. It would be ideal treatment in pyogenic joints to start frequent, prolonged, and complete active motion immediately after operation, but such treatment can be attained only in rare instances. One needs only to see a single case to appreciate the suffering undergone by a patient with such a lesion, and when the average age of these patients is recalled, it becomes obvious that too much cannot be expected of active motion.

Passive motion, extremely gentle in its application, never forced in its degree, repeated several times a day by the surgeon, is much more feasible, and almost if not quite as effective as active motion in the early postoperative treatment. Each joint in this series was thus treated, and active motion substituted for passive as soon as possible. Emphasis must be placed on the *gentleness* of this passive motion. The importance of active motion cannot be overemphasized, but at the same time the usefulness of passive motion should not be overlooked.

6. *The main purpose* in the treatment of acute suppurative arthritis is, of course, the evacuation of the pus by the most efficient means possible. The use of drains and of early passive and active motion was invaluable in accomplishing this in the present series of cases and the fact that these methods when correctly used, are not destructive to infected joints is demonstrated by the end results here reported.

SUMMARY AND CONCLUSIONS

1. An historical review of the treatment of acute suppurative arthritis is presented.

2. Case reports of this disease are scarce in the literature, the results reported are usually bad,

and the attitude of the writers toward the disease is gloomy.

3. The idea of attempting to preserve the function of a purulent joint is relatively recent and is not yet widespread.

4. Thirty six cases of acute suppurative arthritis are presented, in which operations had been performed at the New York Orthopaedic Dispensary and Hospital during the past 15 years.

5. Twenty two of these cases were bacteriologically proved and uncomplicated by bone infection. The end results in this group were 12 or 54 per cent were excellent anatomically, symptomatically, and functionally; 5, or 23 per cent, were good; 1 was fair and 2, or 9 per cent, were poor.

6. Four cases were similar to the above except that they were not bacteriologically proved. Results in this group were 2 excellent and 2 poor.

7. Ten cases were complicated by infection of the bone at the joint. The results in these were much worse than in the above groups, there being no excellent results and five failures due to ankylosis or dislocation.

8. It is thus seen that the presence of bone destruction greatly increases the seriousness of this disease.

9. The average follow up period was 6.5 years. The average age at operation was 6.5 years. There were thrice as many males as females. The hip was involved in 22 cases, the knee in 8, there were 1 elbow, 2 ankles, 1 shoulder.

10. The staphylococcus was the infecting organism in 12 cases, streptococcus in 11, mixed staphylococcus and streptococcus in 4, pneumococcus in 3, mixed streptococcus and Bacillus coli in 1, Bacillus pyocyaneus in 1.

11. In general the best results were obtained in those joints which had early diagnosis and early evacuation of the pus.

12. Active postoperative motion cannot be depended upon as the sole method of continuous evacuation of pus from an infected joint, because of the extreme pain and the usually tender age of the patient.

13. In obtaining efficient continued drainage in this series of cases the most useful adjuncts to arthrotomy were found to be the insertion of soft rubber drains into the joint cavity and gentle passive motion immediately following the operation. The importance of active motion after arthrotomy cannot be overestimated, and this was substituted for passive motion as soon as the patients could stand it.

14. There were no deaths, no amputations, no septicemias, ankylosis occurred only in 4 cases

in which bone destruction at the hip had occurred before operation.

15. The prognosis for function in acute suppurative arthritis is good if the diagnosis is made early and this is promptly followed by arthrotomy and drainage. It is poor if treatment is delayed until bone destruction has taken place.

SUBTOTAL VERSUS TOTAL HYSTERECTOMY

R. S. SIDDALL, M.D. AND H. C. MACK, M.D. DETROIT MICROSKOP

From the Department of Obstetrics and Gynecology, Harper Hospital

THE recent literature concerning hysterectomy for non-malignant pelvic conditions shows a definite trend of opinion toward the employment of the total rather than the subtotal or supravaginal operation. This tendency seems to be due largely to emphasis on the possibility of subsequent development of cancer in the stump of the cervix uteri, though the more radical operation has also been recommended for the relief of cervicitis alone. As apparent justification for this position a majority of the reports seen by us during the last 5 years show very little or even no greater mortality with total than with subtotal hysterectomy (Table I).

TABLE I—MORTALITY IN TOTAL VERSUS SUBTOTAL HYSTERECTOMY

	Subtotal hysterectomy		Total hysterectomy	
	Number	Mortality per cent	Number	Mortality per cent
Masson	317	3	199	3
Kelso		3	476	9
Fullerton and Faulkner	686	4.4	1,073	4
Burch and Burch	166	4	23	3
May and Mayo	2,085		1,586	0
Greenhill	2,877	4.47	153	4.7
Read and Bill	2,730		603	3
Total	7,995	6	4,599	3

From the figures in Table I we can calculate 7,995 subtotals with 199 deaths or a mortality rate of 2.6 per cent, and 4,599 totals with 139 deaths or a mortality of 3.0 per cent. However a critical review of the reports containing these series makes the figures less convincing. The series reported by Mayo and Mayo refers to the hysterectomies for fibroid only which were done at the Mayo Clinic from 1916 to 1929 and includes some of Masson's cases. They believe that in their figures the difference in favor of the subtotal operation may be apparent only because of sampling or the occurrence of graver risks among those selected for the total removal. They further believe that the latter reason also explains the higher mortality for total hysterectomy in other reports. Von Graff expressed the same opinion.

Such reasoning is so contrary to usual surgical practice that we are at a loss to explain it, unless the reference is to operation in the presence of infection of the cervix or of malignancy. In fact, it is not uncommon when a total hysterectomy seems desirable, to be forced to resort to the less formidable subtotal operation on account of poor condition of the patient before or during operation or because of technical difficulties. Read and Bill conclude that subtotal hysterectomy carries less risk "in spite of the fact that it includes those patients who are poor operative risks." Nelson gives as partial explanation for the higher mortality with the supravaginal operation in his series that "it has often been done in poor risks." Moreover in regard to peritonitis he makes the interesting observation that the danger should be as great in cutting through the infected cervix as through the wall of the vagina which "is more accessible and can be more easily sterilized than the cervix." The exceptionally high mortality for the subtotal operation in the report by Fullerton and Faulkner is unexplained. Similar figures in Greenhill's series were due to the unusually high mortality (8.9 per cent) with subtotal hysterectomy plus bilateral salpingectomy in cases with advanced tubal and ovarian infections involving adhesions to adjoining structures. Where hysterectomy alone was done, the mortality was 5.5 per cent for total and only 0.8 per cent for subtotal. The series of Burch and Burch contains too few totals to be of much significance. With the exception of Fullerton and Faulkner all authors who mention morbidity and complications show them to be more frequent with total hysterectomy. Fullerton and Faulkner give their incidence of shock, injured vessels, hemorrhage, etc. as 5.5 per cent for total and 6 per cent for subtotal hysterectomies, the difference (0.5 per cent) in favor of total being reversed if cardiac complications are not included. It might be said also that some, at least, of these statistics were derived from special clinics and therefore cannot be used as a general guide in private practice.

We have undertaken a study of abdominal hysterectomies done at Harper Hospital with the expectation that the figures from this large general hospital might fairly represent the relative results to be expected from the two types of operation in private practice. Our study included

the 5 years from January, 1928, through December, 1932, during which time there were 1,379 abdominal hysterectomies for benign gynecological conditions. This is exclusive of all cases of cervical carcinoma regardless of type of operation. To make the conditions under which the two operations were performed as nearly comparable as possible, we further excluded operations done in the presence of malignancy of the body of the uterus and of the adnexa. Cesarean sections or ruptured uteri followed by hysterectomy were also not included. It is noteworthy, however, that the inclusion of these eliminated cases (80) would have changed the mortality figures only a fraction of one per cent. Of the 1,376 operations 1141 were subtotal hysterectomies with 30 deaths and 235 total with 15 deaths—a mortality rate of 2.6 and 6.4 per cent, respectively. The combined mortality rate was 3.3 per cent.

TABLE II.—HARPER HOSPITAL SERIES SHOWING MORTALITY

Year		Number	Per cent	Mortality Per cent
1928	Subtotal	811		9
	Total	60	7.5	9.1
1929	Subtotal	118		1.9
	Total	61	50.9	6.5
1930	Subtotal	217		5.8
	Total	24	11.5	8.9
1931	Subtotal	290		1.3
	Total	24	13.4	5.8
1932	Subtotal	205		1.0
	Total	19	10.0	5.1
	Subtotal	1,141		2.6
	Total	18	1.7	6.4

Table II gives the number of both operations with their mortality rates for each year. It also shows the yearly percentages of total hysterectomies. The mortality rates for the subtotal operation have remained at a fairly constant level whereas those for the total have tended to diminish. In addition, it is seen that the years with the lower percentages of total hysterectomy had a somewhat lower mortality rate for that operation. On the assumption that possibly the lower rates were due to a tendency to elect the subtotal operation for poor risks, the years 1929 and 1931 were studied. In 1929, the total operation was done on 11 poor risks (hemoglobin below 70 per cent, cardiac disease, nephritis, diabetes), and in 1931 on 10. The subtotal operation was performed on 32 in poor condition in 1929 and 38 in 1931. Because of the small yearly number of

cases, we consider these figures as merely suggestive.

It has been stated in the literature that the apparent advantages in mortality of subtotal over total hysterectomy varied with the skill and experience of the operator, the inference being that the more experienced operators could obtain as low mortality rates with total as subtotal hysterectomy. To test this assertion we investigated the whole group of 235 total operations, and for comparison the 458 subtotals done in 1929 and 1931. The years 1929 and 1931 were selected as being at neither extreme of time and therefore probably representative, the mortality rate, moreover for these periods being the same as for the whole group of subtotal hysterectomies. We found that the 693 operations (total and subtotal) had been done by 46 different gynecologists and general surgeons of greatly different experience as evidenced by the number of hysterectomies performed by each. Two operators did 50 or more during these periods, five, 25 or more and less than 50, thirty-eight, less than 25. Table III shows the comparative mortality rates for these groups. A separate classification was given the clinic cases as these were in large part operated upon by a series of five residents, though under the supervision and usually with the assistance of a senior attending gynecologist. Besides demonstrating the value of experience, this table shows a lower mortality for subtotal hysterectomy in every division, and except in the clinic cases the difference is striking.

TABLE III.—COMPARATIVE MORTALITY OF DIFFERENT OPERATORS

Cases per operator	Subtotal hysterectomy Mortality per cent	Total hysterectomy Mortality per cent	All cases Mortality per cent
50 plus	0.7	4.5	2.2
25 to 49	0.9	4.3	1.9
1 to 24	4.8	11.9	6.6
Clinic	4.8	5.4	5.1

The immediate causes of death with the actual numbers for both subtotal and total hysterectomy are shown in Table IV. In general these figures confirm those usually given except for the higher incidence of infection and peritonitis in our series. The percentage occurrence of these causes was approximately 57 per cent of the subtotal and 73 per cent of the total hysterectomy deaths, or mortality rates of 1.5 per cent and 4.7 per cent, respectively, from these causes alone. Embolus caused deaths in 0.5 per cent with the subtotal

and 0.8 per cent with the total operation. Shock with myocardial failure resulted fatally in 0.4 per cent and 0.8 per cent of the 141 subtotal and 335 total hysterectomies. These statistics show that the usual causes of death (peritonitis, embolus, and shock) were common to both types of operation but occurred to a greater degree in total hysterectomy.

TABLE IV—IMMEDIATE CAUSES OF DEATH

	Peritonitis and collection	Emboli	Shock and myocardial failure	Dissection	Pneumonia	Total
Deaths in 1,741 subtotal hysterectomies	7	6	5	1		19
Deaths in 335 total hysterectomies						1

The influence of accessory procedures at the time of operation was studied in the groups mentioned in Table IV, viz. the 335 totals for all 5 years as compared to the 458 subtotal hysterectomies for the years 1929 and 1931. Removal of the uterus without the adnexa resulted in 1 death in 66 totals and 5 deaths in 174 subtotals—a mortality rate of 1.5 per cent and 2.9 per cent, respectively. With salpingectomy or salpingo-oophorectomy the results were quite different, for with the 147 totals there were 13 deaths (8.8 per cent) and with the 247 subtotals there were 7 deaths (2.8 per cent). Of the 147 totals with salpingectomy or salpingo-oophorectomy there were 80 with definite clinical and laboratory evidence of pelvic inflammation such as extensive adhesions or subacute or chronic salpingitis. The mortality was 10 per cent. In 67 cases with no note of pelvic inflammation there was a mortality of 7.4 per cent. Among the 247 subtotal hysterectomies with the same accessory procedures there were 165 showing pelvic inflammation and 82 without, the mortality being 3 and 2.4 per cent, respectively. It is probable that many cases designated by us as without pelvic inflammation were actually complicated by the condition although it was not so stated in the histories. It is quite evident that the higher mortality of hysterectomy plus salpingectomy and salpingo-oophorectomy was due in part, at least, to difficulties encountered because of pelvic inflammation as was noted also by Greenhill. This observation is supported by the mortality rates of subtotal and total hysterectomy for fibroid with and without pelvic inflammation as shown in Table V.

Of other accessory procedures appendectomy was the most frequent, being done in 83 or 35.3

TABLE V—MORTALITY WITH AND WITHOUT PELVIC INFLAMMATION

	Subtotal Mortality per cent	Total Mortality per cent
Hysterectomy for fibroids without pelvic inflammation	8	3.8
Hysterectomy for fibroids with pelvic inflammation	3	10.9
With and without pelvic inflammation	11	7

per cent, of the totals and in 220 or 48 per cent of the subtotals. Three of the patients in whom total hysterectomy plus appendectomy were done died, a mortality rate of 3.6 per cent as compared to 6.4 per cent for the whole group. There were no deaths among the subtotal cases with appendectomy. We believe these results should not necessarily be interpreted as indicating that removal of the appendix added no danger to hysterectomy but rather that appendectomy was reserved in general for the more favorable cases. Supporting the latter possibility and without taking into account technical difficulties etc. is the fact that among the totals with appendectomy there were 8.4 per cent poor or questionable surgical risks (hemoglobin below 70 per cent, cardiac disease, nephritis, diabetes) as compared to 19.1 per cent for those without appendectomy. Among the subtotal hysterectomies plus appendectomy there were 10.9 per cent poor risks as compared to 19 per cent for the remainder of those done in 1929 and 1931. Other accessory operations such as perineorrhaphy, colporrhaphy, cholecystectomy, and herniorrhaphy were performed in an additional 21 of the totals and 35 of the subtotals—with 1 death among the totals.

DISCUSSION

Our investigations indicate a definitely higher mortality for total hysterectomy than for the subtotal operation. Furthermore we believe that statements in the literature to the contrary are not convincing when the data on which they are based are analyzed. On the other hand, it seems that when hysterectomy is to be undertaken and there is also a definite indication for removal of the cervix, the more radical operation is not unduly dangerous in the best operative risks.

The actual incidence of carcinoma developing in the cervix after subtotal hysterectomy is not known but the possibility is worthy of consideration. Polak estimated the occurrence at 2 per cent a figure which would possibly justify the frequent employment of total operation. But, this is far higher than that stated by other

writers. Von Graff quotes Hochmann as giving 0.27 per cent. Mayo and Mayo reported 99 cases seen at the Mayo clinic from January, 1910, to July 1930, only 15 of these, however being in women who had been operated on there. They believe the low incidence in their own cases was due to coming out the cervical canal from above. This procedure may well be of some importance, but it does not remove the usual site of cervicitis and carcinoma of the cervix—the region of the external os. Of much greater value, we think, is their suggestion that following subtotal hysterectomy the cervix be removed later from below or that enucleation of the cervical canal or cauterization be carried out. In several instances where total hysterectomy seemed indicated but was not done on account of the patient's condition one of us has later removed the stump of the cervix without difficulty, but this has the obvious objection of additional hospitalization. In cases in which the cervix is torn and infected but not sufficiently so to make its removal imperative, thorough cauterization or conization under anesthesia before the abdominal incision is made should accomplish much in preventing carcinoma in the cervical stump. Moreover the rare, very early, and therefore local and unrecognized carcinoma would almost certainly be destroyed. In our series the operation records of the 458 subtotals done in 1929 and 1931 showed only 16 of these accessory operations on the cervix though probably some cauterizations were done later because of persistent leucorrhœa.

SUMMARY

Although there is a definite tendency in the recent literature to ascribe to total hysterectomy a mortality comparable with that of the subtotal operation, a critical study of the reports leaves one far from convinced. In our 5 year series there were 1,376 abdominal hysterectomies (ex-

cluding malignancy, cesarean section followed by removal of the uterus, and ruptured uterus) of which 1,141 were subtotal and 235 total with mortality rates of 2.6 per cent and 6.4 per cent, respectively. There was a tendency for the total hysterectomy mortality to be lower in the years with a relatively smaller proportion of the more radical operation. All groups made on the basis of surgical experience of the operator (number of operations per operator) showed an advantage in mortality for subtotal hysterectomy. Pelvic inflammatory disease made hysterectomy more dangerous and explained in part, at least, the higher mortality of hysterectomy with removal of the adnexa. With accessory operations such as appendectomy and perineorrhaphy, the lower mortality was apparently associated with a selection of the better risks for these additional procedures. The danger of carcinoma developing in the stump of the cervix after subtotal hysterectomy is seemingly not sufficiently great to justify the additional risk of the total operation in any but a small proportion of cases. Other less dangerous procedures should be more frequently recommended.

DIVERTICULA OF THE STOMACH

ANDREW B. RIVERS, M.D. ROCHESTER, MINNESOTA
Department of Medicine, May Clinic

(ARNOLD STEVENS, M.D. ROCHESTER, MINNESOTA
Fellow in Surgery, May Clinic

B. R. KIRKLEN, M.D. ROCHESTER, MINNESOTA
Section on Roentgenology, May Clinic

ANATOMICALLY the term "diverticulum," is applied to a blind tubular process and pathologically to any malformation having this character. Akertund described gastric diverticula as rounded, pocket-shaped or bag-shaped protrusions from the lumen of the stomach. Thus, broadly speaking, the term includes not only true diverticula, whether congenital or acquired, but also diverticular formations resulting from intrinsic lesions of the gastric wall, such as ulcer or neoplasm. In this paper only true diverticula will be considered in detail.

Diverticula occur in the stomach less commonly than in other portions of the alimentary tract with the possible exception of the jejunoileal region. Fraser stated that these lesions occur in the different parts of the alimentary tract in the following order of frequency: colon, rectum, duodenum, pharynx and oesophagus, stomach, jejunoileum. The statistics of Larimore and Graham are in accord with this statement. In a series of 3,446 examinations of the digestive tract with the opaque meal they found 105 diverticula: 71 were in the colon, 19 in the duodenum, 9 in the oesophagus, 3 in the stomach, and 3 in the jejunum.

The first case of diverticulum of the stomach was reported by Helmont in 1804. Since that time we have found 108 cases, either mentioned or reported in detail in the literature. As might be expected, most of these have been reported since roentgenological examination has become available in diagnosis. Many of the cases reported have not been confirmed at operation or necropsy. This detracts materially from the reliability of the reports because of the difficulty in distinguishing roentgenologically true gastric diverticula from false diverticular formations. Our series includes 14 proved cases of diverticula of the stomach.

Four of the specimens of diverticula were obtained at necropsy and 10 were removed at operation. Diverticula of the stomach have been diagnosed roentgenologically in 25 cases at the Mayo Clinic since 1926. In 6 cases of the group exploratory operations revealed only 2 to be true diverticula; in the 4 others, diverticular pro-

trusions were found to be due to perforating peptic ulcer or to carcinoma. The 19 remaining cases, in which diagnosis was made roentgenologically but not proved or disproved at operation or necropsy, are not included because of the frequent confusion in the roentgenologic diagnosis of these lesions.

CLASSIFICATION

Diverticula of the digestive tract have been variously classified as congenital, or true, acquired or false, and pulsion or traction types. True (congenital) diverticula have been considered to have intact muscular and mucosal layers, whereas false (acquired) diverticula have been considered to be those diverticular formations in which one or more of the mural layers are absent. The terms "pulsion" and "traction" are self-explanatory and have been used frequently in connection with true and false diverticula. Kaushch pointed out that the terms "congenital" and true and "acquired" and "false" are not always synonymous. Brandes substantiated this statement by reporting a case of an acquired diverticulum in which all layers of the wall of the sac were present.

It is thus evident that there is much confusion and some inaccuracy in the classification of these abnormalities. In order to simplify the subject of gastric diverticula we suggest the following subdivisions:

1. *True diverticula.* Those in which the pouch includes all coats of the gastric wall without definite evidence that organic disease was the causative factor. Such diverticula probably are congenital (Fig. 1).

2. *Acquired true diverticula.* In these all coats of the gastric wall are present although there may be some thinning, and there is evidence that some disease was instrumental in causing the pouching.

(a) *Pulsion type diverticula* result from intra-gastric pressure which is probably localized.

(b) *Traction type diverticula* are incidental to extragastric adhesions (Fig. 2).

3. *False diverticula or diverticular formations.* In these there is a break in the gastric wall resulting from disease (Fig. 3).

Fig. 1 True diverticulum at the cardiac part of the stomach. The mural elements are intact but are thickened out.

Fig. 2. Acquired true diverticulum of traction type. All layers of the wall of the sac are present, and there is some thinning at the site of the adhesive band.

HYPOTHESES AS TO FORMATION

True diverticula. The etiology of true diverticula is unknown. The question even has been raised as to whether a truly congenital type exists at all. Zahn went so far as to state that no diverticula reported up to 1899 were congenital. Laurell and others expressed the belief that these true diverticula are of the pulsion type and are caused by intra-abdominal pressure among persons with a lax abdominal wall. That this is the true explanation is doubtful since true diverticula have occurred in young muscular adults and in children. Gile reported a case of a girl aged 7 with a diverticulum, and Sinclair one of a 4 months old infant, both being confirmed at operation.

Furthermore as has been demonstrated by Gianturco and others intragastric pressure is ordinarily quite low. At the cardia where most diverticula occur, the pressure is lowest, ranging from 5 to 2 centimeters of water. Alvarez has distended the fresh stomachs of cats and dogs under pressures much greater than those occurring physiologically without producing diverticula. The objection may be raised that this experiment was inadequate, and that continued or repeated pressure would be necessary for the development of diverticula. On the other hand, Fraser consistently produced multiple diverticula in the jejunum by briefly distending this part of the bowel; he thus confirmed his belief that jejunal lesions could be acquired.

Despite views to the contrary, it seems to us that the weight of evidence favors a congenital basis for this group of gastric diverticula. Diverticula are not uncommon in lower animals especially in the pig. The tip of the fundus in this animal normally develops as a diverticulum. The sloth of South America has a cardiac diverticulum normally (Alvarez). However the fact that this animal virtually lives in an inverted posture might be interpreted by exponents of the idea as adding weight to the hypothesis that diverticula are acquired by pulsion. The beaver has a projection of the pylorus at the greater curvature of the stomach. The fish *Lophius piscatorius* or angler has protrusions from the pylorus at each curvature and the American aquatic herbivorous mammal the manatee, has three diverticular compartments namely, at the pars media on the greater and lesser curvatures and at the cardia (Huntington). All ruminants, as well as certain forms of aquatic life such as the *Argyroneta aquatica*, *Asterias rubens* and others, have similar gastric compartments (Buetschli).

In attempting to explain the occurrence of diverticula of the stomach in man embryologically, Kalbfleisch stated that the fundus of the stomach of man develops as a pouch on the outer side of the cardia. He expressed the belief that, in congenital diverticula, another smaller pouch develops and remains connected with the stomach by a narrow neck. This hypothesis would

Fig. 3. False diverticulum due to weakening of the gastric wall by ulcer.

explain only those diverticula that occur at the cardia. It is interesting to note that diverticula of the pyloric region have not infrequently been found in association with aberrant pancreatic tissue. Nauwerck, Falconer, Weischelbaum, Kolb, Wagner and Gegenbauer found pancreatic tissue in such diverticula. Gille demonstrated heteroplasic colonic mucosa in a gastric diverticulum, and pancreatic tissue adjacent to it.

Anatomically, there is thinning of the circular and oblique muscular fibers at the cardia. Large vessels that enter the gastric wall in this region also contribute to the muscular weakness and make it a site of lowered resistance. Thorel and Zahn believed that this part of the stomach was subject to the greatest strain as food passed along the *Magenstrasse*.

In view of the fact that diverticula of the type under consideration have been found in all regions of the stomach, and almost uniformly present muscular and mucosal elements, which are thin, it seems possible that these diverticula may occur as a result of a congenital localized weakness of the gastric wall. The natural anatomical weakness at the cardia and the frequent presence of pancreatic tissue at the pylorus, could account for the relative frequency of diverticula at these sites. On the other hand, the thinness of the wall of the sac may be secondary to pressure of gastric contents accumulating in the diverticulum. Such a hypothesis would fit in with the conception that diverticula, as such, exist as vestigial phenomena. It would at least seem reasonable to assume that congenital, anomalous conditions precede develop-

Fig. 4. The situation of the diverticula in our series of cases.

ment of such an abnormality if it does not already exist at birth.

Acquired true diverticula. The etiology of this type of diverticulum is usually obvious. Adhesions to the gall bladder, pancreas, and spleen are probably the more common factors producing traction. Jones reported a case in which the gastric wall was adherent to the gastroduodenal ligament and colon. Kalbfleisch expressed the belief that this case was probably one of ulcer. Castro described a case of diverticulum with adhesions to the abdominal wall at the site of a hernia. Von Hansemann reported another case with adhesions to an epigastric tumor. A pulsion diverticulum was caused by a trichobezoar in a case reported by Schulten.

Acquired false diverticula. The gastric wall may be weakened by inflammatory reaction, ulceration, or by neoplasm. It is conceivable that intra-gastric pressure or progressive ulcerating processes could produce pouching at the site involved.

REVIEW OF MATERIAL IN THIS SERIES

Incidence. Ten specimens in our group were removed in 10 of 11,334 consecutive exploratory operations on the stomach, or 1 in 1,133.5. Four specimens were obtained in the course of 3,663 routine postmortem examinations, or 1 in 917. Twenty-five roentgenologic diagnoses of gastric diverticulum were made in the course of 91,532 routine roentgenologic examinations of the stomach at the clinic since 1926. As has already been mentioned, many of these were probably not true diverticula.

Fig. 5 True cardiac diverticulum specimen obtained at necropsy

Age. The ages of the patients in this series ranged from 25 to 59 years 9 were 40 years of age or older and 5 were from 25 to 40 years of age. The average age was 42 years.

Sex. Diverticula occurred about equally often in either sex 6 of the patients were men and 8 women.

Situation. The situation of diverticula in cases reported in the literature varies but they seem to occur most often in the cardia, just below the esophageal juncture on the posterior wall and usually nearer the lesser than the greater curvature. According to reports they occur next most often at the pylorus, near one or the other curvatures. In our series of proved cases 6 diverticula were found immediately adjacent to the pylorus, 6 at the cardia, and 2, some distance from the pylorus on the posterior wall (Fig. 4).

Pathologic findings. Diverticula of the stomach in proved cases reported heretofore have varied in diameter from 1 to 5 centimeters. In our group the smallest diverticulum was 1 centimeter in diameter and the largest, 7.5 centimeters (3 inches). The neck of the sac is usually narrow and may or may not be thickened. Grossly, the mucosal and serosal surfaces appear intact. Microscopic examination of sections of the wall of the sac reveal the presence of the mucosal and muscular layers but these are thinned out. Pancreatic tissue was not found in the diverticulum in any

Fig. 7 Section of wall of true diverticulum. All layers are intact but are thinned out. $\times 655$

Fig. 6 True diverticulum at the cardiac end of the stomach. Specimen obtained at necropsy with esophagus intact.

of our cases (Figs. 5, 6, 7, 8). Acquired, or so called false diverticula, may have a deficiency of the mucosal layer or of one or more muscular layers, or both, and the serosa often gives evidence of adhesions to adjacent viscera.

Associated gastric disease. Associated gastric disease was found in 4 of our 14 cases (30 per cent). In 2 cases, there were ulcers adjacent to the diverticula (in 1 case at the cardia, and in the other at the pylorus); in 1, an adenomyoma in the diverticulum and a duodenal ulcer and in the remaining case a sarcoma in the wall of the diverticulum. What part, if any the adenomyoma and the sarcoma played in the development of the

Fig. 8. Wall of normal stomach adjacent to diverticulum. $\times 655$

diverticulum is problematic. Cleve, Puskepelles, and Nauck considered that such lesions developed in pre-existing diverticula, whereas Bell and Golden doubted whether these should be classed as true diverticula. The literature contains reports of a number of cases with associated disease similar to those in our group. Cleve reported a myoma in a diverticulum, Sandstrom a diverticulum with a benign adenoma, and C. H. Mayo, von Hanseemann, Miller and Mellon and others cancerous or precancerous changes in diverticula.

Two or more diverticula in the gastro-intestinal tract. Of the 14 cases included in this report in 2 demonstrable diverticula were present elsewhere in the digestive tract. In 1 case, multiple diverticula in the colon were found and in another a duodenal diverticulum was found.

SYMPTOMS

The general opinion of writers on the subject is that most diverticula of the stomach cause no definite symptoms and are usually not of clinical importance. However some cases have been reported in which there was epigastric distress, positive roentgenologic evidence, and apparent relief following surgical treatment.

In 1 case of our group the patient complained of hæmatemesis, and blood clots were found in the diverticulum. Definite evidence of blood dyscrasia developed later. In 4 cases part or all of the symptoms may have been attributable to the diverticulum in 4 the complaint was accounted for by associated gastric or duodenal ulcers, and in 1 a sarcoma may have been responsible for some of the symptoms. Thus in 10 of the 14 cases (71 per cent) symptoms could not be attributed to the diverticulum *per se*. In the 4 cases (excluding the one with hæmorrhage) in which the symptoms may have been related to the diverticula epigastric pain was present which might or might not be relieved or aggravated by food, in 2 vomiting had occurred on several occasions (in 1 case probably due to cardiospasm) and in 3 epigastric tenderness was present.

DIAGNOSIS

The recognition of a true gastric diverticulum without the aid of the roentgenogram is impossible, as there is no characteristic clinical syndrome (Fig. 9). Even the roentgenologic findings are difficult to interpret, as is evident from the fact that in 4 of 6 of our cases in which the diagnosis had been diverticula these diverticula were found at exploration to be false sacs due to malignant disease or to perforating ulcer. The 2 cases in which true diverticula were found were the only

cases in our group of proved cases in which the pre-operative diagnosis was correct. Both of these diverticula were at the cardia. However one is probably justified in making a diagnosis of diverticulum when the roentgenologic findings are consistent and the patient has epigastric distress which is not attributable to other disease.

A number of writers stress the difficulty of roentgenologic diagnosis. Sandstrom said that the diagnosis depends on a niche like opaque spot surrounded by a defect in the contrast shadow, the appearance of which is also typical of ulceration with surrounding infiltration. Pendergrass outlined the differential diagnosis of diverticulum and hernia through the oesophageal hiatus. He stated that hernias are best seen with the patient in the recumbent Trendelenburg position and that they are larger during inspiration and smaller during expiration because of variations in intra-abdominal pressure. A gastric diverticulum on the other hand, does not reveal these changes.

COMPLICATIONS

A complication occurred in but one (7.1 per cent) of our proved cases, in this instance being hæmorrhage. This case has previously been reported by Sutherland. Hæmorrhage also has been reported by Brown, Akerlund, Gale, and by Sinclair.

TREATMENT

The treatment in 10 cases of our series was surgical. The diverticula were removed by local excision by sleeve resection of the stomach, or by pylorotomy. When gastric or duodenal lesions were associated with diverticula, the surgical procedures were modified according to the type of disease that obtained. The indication for treatment of a diverticulum in the upper portion of the stomach rests on a positive roentgenologic diagnosis plus the presence of epigastric distress not referable to other disease.

Bell and Golden felt that postural drainage should be tried in cases of diverticula at the cardia, as carcinoma has never been reported in this group. They believed that surgery should be performed in all cases in which the lower two thirds of the stomach was involved, because of the possibility of associated malignant disease and the frequently mistaken roentgenologic diagnosis of diverticula in this region. In the light of the present study we are led to concur in this opinion. The consensus of opinion favors excision of the sac as the procedure of choice, although inversion of the diverticulum, gastro-enterostomy and gastric resection have been performed in some instances.

REPORTS OF CASES

SURGICAL.

CASE 1. A man, 36 years of age, came to the clinic because of stomach trouble of 3 to 4 years' duration. He complained of a "hot spot" in the upper portion of his abdomen that had been more or less constantly present but had never been aggravated by heavy foods. He made the statement that it felt as though a sac were present near the entrance of the stomach, because there was a dull pain in this region similar to that caused by food packed in the socket of a tooth. Epigastric tenderness was present.

Analysis of gastric contents revealed a total acidity of 60, free hydrochloric acid of 40, and a total quantity of 140 cubic centimeters. The roentgenologic diagnosis was diverticulum of the cardiac end of the stomach. Other findings were irrelevant.

Exploration revealed a diverticulum at the cardia immediately below the esophagus, passing to the left and along the fundus of the stomach. The diverticulum was excised. The pathologist reported that the diverticulum was 3 by 4 centimeters in diameter with thinned out muscular and mucosal layers.

One year later the patient reported that he was well.

CASE 2. A woman, 38 years of age, complained of abdominal distress of 12 years' duration. The symptoms had been somewhat indefinite. She stated that the region of maximal distress was situated to the left of and above the umbilicus, although pains elsewhere in the abdomen were not infrequent. Belching and alkalies were said to have given relief, whereas food had had no effect on her symptoms unless at times to aggravate them. She occasionally had awakened at night with epigastric pain that usually had radiated to the sternum. She presented the multiple, bizarre complaints so often encountered in neurotic persons.

General physical examination gave negative results. Analysis of gastric contents revealed a total acidity of 44, free hydrochloric acid of 32, and a total quantity of 100 cubic centimeters. The roentgenologic diagnosis was diverticulum on the posterior wall of the cardia.

At operation, a diverticulum was found on the posterior wall of the stomach at the cardia and also an ulcer next to the pylorus. The lesions were excised. The pathologist reported that the diverticulum was 2.5 centimeters in diameter with an opening into the stomach 1 centimeter wide.

CASE 3. A man, 43 years of age, complained of a dull, aching pain in the upper portion of his abdomen, of which he had been aware for 1 year. The pain had been constant and had been somewhat intensified after meals. Some epigastric tenderness had also been present.

Analysis of gastric contents revealed a total acidity of 70, free hydrochloric acid of 50, and a total quantity of 175 cubic centimeters. The roentgenologic diagnosis was prepyloric ulcer.

At exploration, a diverticulum, 4 centimeters in diameter, was found on the greater curvature and removed by resection of the pyloric third of the stomach. A posterior Polya anastomosis was made. The pathological diagnosis was diverticulum.

CASE 4. A woman, aged 30 years, entered the clinic because of stomach trouble during the previous 4 years. She complained of pain in the epigastrium following a heavy meal, which had been relieved by emesis and massage of the abdomen and partially alleviated by taking soda. Slight epigastric tenderness was present.

Analysis of gastric contents revealed a total acidity of 40, free hydrochloric acid of 32 and a total quantity of 35 cubic centimeters. The roentgenologic diagnosis was duodenal ulcer with moderate retention.

Fig. 9. Diverticulum of cardia. Fluid level is evident.

A diverticulum producing obstruction, a centimeter from the pyloric ring on the gastric side, was discovered. Pylorectomy was performed. The diagnosis of diverticulum was confirmed pathologically.

CASE 5. A woman, 26 years of age, came to the clinic because of dysphagia and spasmodic substernal pain that had been present for 10 months. She also had had pain in the epigastrium from 1 to 2 hours after meals. There had been some regurgitation at times. Dilatation of the esophagus had relieved the substernal pain, but had failed to affect the distress in the epigastrium.

Exploration revealed a diverticulum, 3 inches (7.5 centimeters) deep at the lower margin of the stomach near the pylorus. The lesion was excised and the pathologist's report confirmed the diagnosis.

Eighteen years later the patient complained of symptoms referable only to cardiospasm.

CASE 6. A man, 51 years of age, entered the clinic because of weakness, anemia, and tarry stools during the previous 9 months. Examination of the blood revealed that the concentration of hemoglobin was 43 per cent, that erythrocytes numbered 3,120,000 and leucocytes 8,100 per cubic millimeter and that the color index was 0.7 per cent. There was a total gastric acidity of 90, free hydrochloric acid of 73 and a gastric content of 80 cubic centimeters. The roentgenologic findings were suggestive of a benign lesion at the pyloric end of the stomach.

On exploration, two diverticula containing clotted blood were found on the posterior wall of the stomach near the greater curvature and about 3 inches (7.5 centimeters) from the pylorus. The lesions were excised by sleeve resection of stomach. Pathologist's report confirmed diagnosis.

Definite signs of a blood dyscrasia developed later.

CASE 7. A man, 50 years of age, complained of vague, gastric intestinal disturbance not characteristic of any definite disease. Roentgenologic diagnoses was carcinoma of the stomach. A tumor on the posterior wall, 3 inches (7.6 centimeters) away from the pylorus was removed. The pathologist reported that the lesion was a diverticulum, 3 centimeters long, with a fibromyxoma starting in the submucosa. The patient died subsequently from extension of the malignancy.

CASE 8. A man, 40 years of age, was operated on because of gastro-intestinal symptoms indicative of peptic ulcer. A diverticulum was found contiguous to a perforating ulcer at the pylorus. Excision and a Finney type of pyloroplasty were performed. The surgical findings were confirmed pathologically. Six years later gastro-enterostomy was performed for recurrence of symptoms.

CASE 9. A woman, 30 years of age, was operated on because of symptoms ascribed to peptic ulcer. A duodenal ulcer was found. Adenomyoma in a diverticulum with an opening 2 centimeters in diameter also was present. The diverticulum was on the lower border of the stomach, just proximal to the pylorus. Excision of the diverticulum and gastro-enterostomy were performed. The pathologist's report was confirmatory. Three months later the patient wrote that she was cured.

CASE 10. A woman, 50 years of age, was operated on because of symptoms indicative of peptic ulcer. A duodenal ulcer and a diverticulum, 1 centimeter in diameter in the pyloric region, were excised. A Billroth I anastomosis was performed. The surgical diagnosis was confirmed pathologically. One year later the patient complained of stomach trouble.

POSTMORTEM

CASE 1. A woman, 56 years of age, died following surgical drainage of an appendical abscess. Necropsy revealed among other lesions a large diverticulum of the caecum and diverticula of the colon.

CASE 2. A man, aged 40 years, died of cardiac and renal disease. Necropsy revealed among other lesions a diverticulum, 1 by 3 centimeters which was situated 4 centimeters from the cardia.

CASE 3. A woman, 44 years of age, died following hysterectomy for carcinoma of the uterus. Necropsy revealed among other lesions a diverticulum, 1 by 3 centimeters in diameter situated 8 centimeters below the oesophagus. A duodenal diverticulum also was found.

CASE 14. A woman, 55 years of age, died of carcinoma of the oesophagus. Necropsy revealed a diverticulum of the cardia partially covered by epithelium of the oesophageal type.

SUMMARY AND CONCLUSIONS

An effort has been made to review in some detail a relatively large group of diverticula of the stomach seen at the Mayo Clinic.

Diverticula in the stomach are rare and, to our knowledge, only 141 cases have been mentioned or reported in detail to date, including our 33 cases, 19 of which were not proved.

In 10 (74 per cent) of the 14 proved cases which we report, there were no symptoms referable to diverticulum in 4 symptoms which may have been related to diverticulum were present.

The cause of true diverticula of the stomach is not definitely known. The hypothesis that they

are congenital is plausible. The cause of the acquired types usually is obvious.

The situation of gastric diverticula in cases reported in the literature was most often at the cardia and next most often at the pylorus, although they have occurred in every portion of the stomach. In our series the diverticula were equally distributed at the cardiac and pyloric regions of the stomach.

Associated peptic disease was present in 4 of our 14 cases (30 per cent) and consisted of gastric ulcer, duodenal ulcer, adenomyoma, and sarcoma. Similar associated lesions have been reported in cases in the literature.

The diagnosis is difficult. In our series 4 of 6 pouches diagnosed roentgenologically as diverticula proved to be pouches which developed as a result of perforating ulcers or malignant lesions.

Complication occurred in only 1 of our cases and in that instance, consisted of hemorrhage. Such hemorrhages have been reported by other writers.

In view of the fact that it is extremely difficult to ascertain with accuracy the nature of a diverticulum of the stomach, it would seem to us that with roentgenologic evidence of such a condition and the presence of indigestion, it would be safer to advise surgical exploration.

IDIOPATHIC DILATATION OF THE SYSTEM OF EVACUATION

SURGEONS who perform operations on the sympathetic nerves to the viscera in the pelvis are becoming familiar with coexistent dilatation of the sigmoid colon and possibly rectum, the urinary bladder and the ureters. As a rule the primary object of the operator has been to relieve the symptoms of Hirschsprung's disease by sympathectomy and the dilatation of the lower urinary tract has not been suspected. Although there is still doubt as to the exact nature of the lesion that leads to the pathological changes in the colon characteristic of Hirschsprung's disease, the present consensus is that a congenital defect in the neuromuscular mechanism of the distal part of the colon is present. The proportion of cases of idiopathic dilatation of the colon that is associated with dilatation of the lower urinary tract is still unknown but it is high enough to direct attention to the probability and it is likely that the routine investigation by intravenous urography of patients suffering from Hirschsprung's disease will

show the association to be common. In such cases the obstruction to the outflow of urine from the ureters and the bladder appears to result from achalasia at the ureterovesical junctures and at the internal sphincter of the bladder respectively.

It is probably of significance that the dilated structures receive their sympathetic innervation from the same source—the superior hypogastric plexus or presacral nerve—and this view is supported by the degree of success that has attended efforts to overcome these neuromuscular obstructions by resection of the nerve. A single anatomical lesion cannot be responsible for all the cases that fall into this broad group for indubitably the dilatation may be confined to the colon to the ureters and bladder to the bladder alone or to one ureter. The pathology of the condition is even more obscure.

Of more practical moment to the surgeon is the early recognition and if possible correction of this state of affairs. The lesions involve the structures that are concerned in the final ridding of the body of its waste products—the system of evacuation—and inefficiency of this system must sooner or later prove fatal. Sympathectomy for Hirschsprung's disease appears to be a well tried and satisfactory operation. One of the most important factors in determining its effect on the urinary tract appears to be the state of the walls of the ureters, for long continued stasis and infection of urine may lead to changes of a chronic inflammatory nature which destroy their contractility. But the whole matter is far from surgical finality.

J. R. LEARMONTH

THE SURGICAL TREATMENT OF HYPERTENSION

ONE of the latest developments in the field of surgery of the sympathetic nervous system is the treatment of hypertension. Secondary forms of hypertension, such as those associated with nephritis and arteriosclerosis, as well as the paroxysmal form associated with suprarenal tumors, are not included in the group to be considered for this type of surgery.

The type of hypertension that has responded to operations on the sympathetic nervous system is the primary or constitutional form which occurs among comparatively young people. It is progressive in spite of medical treatment, and carries a prognosis comparable to that of malignant neoplasms. This severe type of essential hypertension may be designated as the malignant type. Because no definite etiological factors have been found, it has been assumed that a constitutional neurogenic abnormality plays an important part in the disease. Following this assumption, and because vasospastic diseases which are due to neurogenic imbalance have been relieved by sympathetic ganglionectomy, operations on the sympathetic nervous system have been carried out in an attempt to relieve hypertension.

There is close parallelism between the disturbed vasospastic mechanism of Raynaud's disease and that of primary hypertension. In both conditions hyperactivity of the vasomotor center in the brain is believed to be at fault. Since surgical interruption of the vasomotor fibers to the extremities relieves the symptoms of Raynaud's disease, it is rational to believe that interruption of the vasomotor nerves to a large portion of the vascular tree would have a depressor effect.

Among the first operations for relief of hypertension were sympathetic denervations of the upper and lower extremities. This did

not affect a sufficient portion of the arterioles to modify the systemic blood pressure, and so, desiring to denervate not only the vessels of the lower extremities but also those of the abdominal cavity, the spinal roots from which sympathetic fibers proceed to the latter region were divided. In order to accomplish this, it seemed necessary to perform laminectomy and rhizotomy of the anterior and posterior roots from the sixth thoracic to the second lumbar segments, inclusive.

Following this operative procedure there was noted a definite and significant drop in blood pressure. In addition to interruption of the vasomotor fibers, there was paralysis of the abdominal muscles, which reduced the intra abdominal pressure. While the desired effects on the blood pressure were achieved, the procedure was considered too radical as a routine form of treatment and a less hazardous procedure was sought. In view of the fact that the splanchnic nerves carrying the sympathetic fibers from the anterior roots to the abdominal viscera could be approached by a less extensive operation they were resected as they entered the abdominal cavity between the crura of the diaphragm. Following this type of operation, a definite drop in blood pressure occurred and definite relief of symptoms was noted in milder and earlier cases, although results did not seem so satisfactory in the more advanced cases. For that reason the previously described rhizotomy was modified to the extent that only the anterior roots were divided. This procedure proved effective in bringing about a significant lowering of blood pressure.

A further modification of this type of operative procedure consisted of the division of the ninth thoracic to the second lumbar roots inclusive, in an effort thereby to produce a maximal drop in blood pressure with a minimal amount of risk.

Several important observations have been made following the two types of rhizotomy. There have been no noticeable deleterious effects, except possibly slowing of the excretion of water which has not resulted in serious complication. Absence of sweating over the abdomen and lower extremities testifies to the division of the vasomotor fibers. There is a postural drop in blood pressure in that the pressure is higher when the patient is prone and lower when the patient is erect. Lessened response in blood pressure to psychic, thermal and pain stimuli has been noticed and marked change in the mean levels of both diastolic and systolic pressures has been maintained over a sufficient time to indicate definite therapeutic value.

It may seem radical to advise resection of the splanchnic nerves or extensive laminectomy and rhizotomy for patients who have this type of hypertension but who have very few symptoms, yet, in the light of experience it would seem that if operation is to be done at all it should be done before

changes in cerebral, retinal, and renal arteries are too advanced.

In spite of the fact that cases are on record in which patients have been followed for two years after splanchnic resection and four years after rhizotomy and beneficial effects have persisted for these periods of time this type of treatment of hypertension should be considered as investigative and more or less experimental until a larger series of patients have been treated and more time has elapsed for postoperative observation. If surgery of the sympathetic nervous system should prove of as permanent value in the control of progressive primary constitutional hypertension as it has in the treatment of some of the vascular diseases affecting the extremities and of other conditions in which hyperactivity of the sympathetic nervous system has been of etiological importance, then it will have achieved another victory in the treatment of a disease which has been found to be resistant to all other forms of therapy.

WINCHELL MCK. CRAIG

HARRY M. SHERMAN
1854-1921

MASTER SURGEONS OF AMERICA

HARRY MITCHELL SHERMAN

HARRY MITCHELL SHERMAN the first specialist in orthopedic surgery on the Pacific Coast was born in Providence, Rhode Island, November 23, 1854. His paternal ancestor came from England in 1633. On his mother's side, the family were descendants of an old French Huguenot family, Mauran by name.

His preliminary education was in St. Paul's School, Concord New Hampshire, and in 1877 he was graduated as Bachelor of Arts from Trinity College, Connecticut. His medical degree was from the College of Physicians and Surgeons, New York, in 1880, which college later became the Medical Department of Columbia University. In that same year, Trinity College granted him the degree of Master of Arts. His hospital internship was in Bellevue, New York, and he served for a time as assistant surgeon at West Point Foundry, New York. In 1881, he became assistant to Dr. Murdock at Cold Spring-on-the-Hudson, and later had some experience as ship surgeon on one of the steamships of the Alexandre Line.

In February, 1885, he came to San Francisco and entered practice, soon becoming associated with the late Dr. George Chismore, the eminent urologist.

Since he had had special training in orthopedic surgery with Dr. Lewis A. Sayre in Bellevue, he recognized in San Francisco an opportunity to develop that specialty, which until then had been in the hands of general surgeons.

In 1886, he became orthopedic surgeon to the Children's Hospital, San Francisco, organized in 1875 by a group of women headed by Dr. Charlotte Blake Brown, and he soon made that institution the center of orthopedic surgery on the Pacific Coast.

In 1890, he married Matilda Barreda, daughter of Frederick Barreda, Peruvian minister to the United States. Mrs. Sherman died in 1895, leaving one son, Frederick Barreda Sherman. In 1896, Dr. Sherman spent a year in Vienna, studying orthopedics.

In 1900, Dr. Sherman married Lucia Hamilton Kittle, daughter of J. G. Kittle, of Ross, California. Of this marriage there were two daughters, Lucia Kittle and Isabel, who, with the son, Frederick Barreda, and Mrs. Sherman, survive.

Dr Sherman suffered from asthma for a number of years, but notwithstanding this handicap he had an unusually full professional life with great accomplishment. Finally his heart broke down after an attack of influenza, and he died May 15 1921.

Dr Sherman was made clinical professor of orthopedic surgery in the University of California in 1896 and professor of the principles and practice of surgery in 1899, which position he held until 1912. In 1901 he was appointed surgeon to St. Luke's Hospital, San Francisco, where he did much operative work. He recognized that in cleft palate work he could see in the depth much better if he had dark instead of white draping. He therefore experimented with colors in the operating room and finally hit upon dark green tiling and dark blue draperies and gowns as most restful to the eye, favoring illumination of the depth of surgical wounds. Like other of Dr. Sherman's original notions, the green color has been chosen for the tiling of operating rooms in numerous other institutions.

He was an active member in many surgical organizations—The American Orthopedic Association, 1899 (president in 1900), The American Surgical Association, 1905. In 1912 he was one of the organizers of the San Francisco Polyclinic and later did yeoman work in organizing the American College of Surgeons in California, of which organization he was one of the governors. It is of some interest to note that after the San Francisco earthquake and fire of 1906 Dr. Sherman was the inspiration for the opening of a teaching hospital for the University of California Medical Department—he started with one bed and one patient, he himself furnishing the equipment—an institution which has become one of the most prominent teaching hospitals in the country.

While Dr. Sherman's chief work was in orthopedics, he did not limit his efforts to that specialty, but did much creditable work in other fields—cleft palate surgery of the spleen, surgery of tumors and even brain surgery. He did much experimental work on suture of heart wounds. He operated a number of times for the removal of the gaseric ganglion for facial neuralgia, and it is fair to assume that the broader view of pathological problems thus acquired reacted to the betterment of his orthopedic surgery.

Endowed with tireless energy, he gave much time and thought to matters of public welfare. In his relations with his fellow man, he was always the gentleman in the best sense of the word.

In the late war, having been for some years an officer in the Medical Reserve Corps of the United States Army, he was called to active duty with rank of major and served as surgeon in command of the Army Hospital at Fort Rosecrans, San Diego, until the end of the War. As a teacher, and in his clinical work, he was painstaking to an extreme and his private and hospital records are models of concise systematic work, largely in his own hand.

Of Dr Sherman's contributions, perhaps the following are most noteworthy

Open operation for congenital dislocation of the hip, in which he overcame the usual rotation of the femur by an infratrochanteric osteotomy, holding the fragments in proper position by means of drills or spikes incorporated in the plaster-of paris dressing. A more fundamental idea was the use of sterile salt solution as a filling for cavities in bones and other places, Sherman making the point that the fluid was eventually replaced by blood into which bone gradually grew and the irritation from foreign bodies such as the various pastes which had been previously used, was avoided.

He invented an extremely useful instrument, a spreader for opening plaster of paris splints.

In 1902 he presented a notable paper before the American Surgical Association on the surgery of the heart.

Dr Sherman's position as surgeon is not to be measured by his contributions to literature, for they were not numerous though of telling quality, but by his influence on those who came into contact with him, for they could not fail to catch some of his enthusiasm. He was a careful and thorough clinician, an excellent operator, a splendid teacher who had the faculty of attracting young men to his work and it is noteworthy that the present generation of orthopedic surgeons in San Francisco were nearly all Sherman's students.

EDMET RIXFORD

EARLY AMERICAN MEDICAL SCHOOLS

THE HISTORY OF RUSH MEDICAL COLLEGE

GOLDER LEWIS McWHORTER, M.D. Ph.D., CHICAGO

RUSH MEDICAL COLLEGE was granted a charter on March 2, 1837 antedating that of the city of Chicago by several days. It was the only medical school in Chicago until 1859 and the only one of five pioneer medical schools in that vicinity to continue without interruption to the present time.

Largely to Daniel Brainard (Fig. 1) must be given the credit for its establishment and early development. Arriving in Chicago in 1836 only two years after his graduation from Jefferson Medical College, he soon demonstrated unusual foresight, ambition, and executive ability. Chicago, at this time, was a rapidly growing village of three thousand. In the adjacent community were many practitioners who had received either no medical education or had failed to graduate, while only about 30 per cent of them were medical graduates. Due to the poor transportation, the demand for physicians was great and the expense together with the inaccessibility of the few eastern medical schools placed the study of medicine largely beyond the reach of possible students from the local community.

Resulting from the local need at this time, there developed five pioneer medical schools in the vicinity of Chicago.

The medical department of LaPorte University was founded in 1842. It became the medical department of Indiana Medical College in 1848 and was discontinued in 1850.

Franklin Medical College was organized at St. Charles, Illinois, in 1842 and discontinued in 1849.

The medical department of Illinois College at Jacksonville was established in 1843 and discontinued in 1848.

Rock Island Medical School was organized in 1848, moved to Davenport, then to Keokuk, and later became a part of the University of Iowa.

Rush Medical College was named after Dr. Benjamin Rush (1745-1813) of Philadelphia. He was one of the foremost medical men and citizens of his time, a graduate of Princeton in 1760, Edinburgh in 1768, professor of medicine in the University of Pennsylvania, a signer of the Declara-

tion of Independence, and treasurer of the United States mint from 1799 to 1813.

In his publications in 1854 Daniel Brainard did not appear to favor the name Rush. He termed himself professor of surgery of the Medical College of Illinois at Chicago and later called it the Medical College of Chicago without mentioning the name Rush. Perhaps the lack of more than grateful appreciation by the relatives of Rush, to the commemoration of his name at a time when the College was in serious financial straits was the reason.

Although a charter was obtained in 1837 with the expectation of an early opening of the school, economic conditions were very bad and it would probably not have opened in 1843 but for the organizing of the schools at LaPorte and St. Charles. This forced Daniel Brainard to open Rush sooner than he wished.

As a result an announcement was issued in October 1843 stating that the first session would begin December 4, 1843 and continue for 16 weeks, before obtaining a college building. The lectures were given in the second story of a frame building occupied by Dr. Brainard as his office and next door to his home, at 49 South Clark Street, at the south east corner of the alley south of Lake Street. The requirements for the degree of doctor of medicine were, "Three years study with a respectable physician, two courses of lectures, one of which must be in this institution (or two years practice will be received in lieu of one course). The candidate must be 21 years old of good moral character, must present a thesis on some medical subject of his own composition, and in his own handwriting which shall be approved by the faculty, and pass a satisfactory examination on all the branches taught in this College.

The first course was given to a class of 22 students with one graduate. The instruction was given by four men with an average of four lectures a day. From the first, clinical teaching was established in the dispensary. This was opened by Dr. Blaney in 1839 as the first free dispensary in Chicago. Upon the opening of the College

in this block in 1843, it was transferred to the College quarters. In 1845 this dispensary was moved to Wolcott and Kinzie Streets and called the City Dispensary. Later it was adopted as a county institution.

During the summer of 1844 a building for the College was erected north of the river at Indiana and Dearborn Streets at a cost of about \$3500.00 (Fig. 2). This served without a change for eleven years. The land was donated by interested real estate men while the faculty and a few others furnished the money.

Austin Flint, as professor of medicine, gave the introductory address in the new building the first annual anniversary of Rush. He remained only one year, due, partly to an inadequate income from the ticket fees by the students.

Medical instruction at first given by a few of the leading physicians in the larger communities was now rapidly taken over by these pioneer medical schools. With the phenomenal growth of Chicago and the strong faculty at Rush it soon became the dominant medical school. There was also considerable feeling against them in the smaller communities because of the necessity for grave robbing and many gruesome tales are told of these early teachers of anatomy and their students who had to obtain their own specimens for dissection. The robbing of a grave at St. Charles caused local indignation to run high with the death of one student and the closing of that medical school in 1849. It was not until 1885 that the State of Illinois legalized the disposition of unclaimed bodies to medical institutions for use in teaching.

By 1850 three of the other five pioneer medical schools had discontinued and a fourth had moved west of the Mississippi River. Five hundred and thirty-two students had studied and 132 had graduated from Rush which had now become strongly established.

While these pioneer medical schools were often referred to as "proprietary" this was not literally the fact, although the property rights did rest with boards of trustees which included medical men.

Among the original seventeen trustees of Rush, only one was a physician and he was not on the faculty. However, shares of stock in Rush Medical College were issued and sold largely to the faculty members who from time to time, were called upon to finance the institution. Dividends were also paid upon this stock.

In the summer of 1850 Chicago had a population of over 25,000. The United States Marine Hospital located only a short distance from the

Fig. 1 Daniel Brainard, 1818-1866

College was nearing completion. Professor Herick of the College assumed charge and clinics were held there in 1853-54.

The Illinois General Hospital of the Lakes, or the "Lake House" was organized with a living in department. It came under the management of the Sisters of Mercy and after the first year was called Mercy Hospital. In 1851-52 Professors Brainard and Davis were in charge of the surgical and medical services and held clinics there. In the College announcement of that year there appeared, but not without some objection, the notice that the requirements of graduation would include hospital attendance.

In 1855 the College building was enlarged to accommodate about 250 students at a cost of \$15,000.00 sustained by the faculty. A museum was included with space for many specimens which had been collected by Professor Brainard in Europe.

In 1856 the College announcement contained a defence of hospital ward teaching as practiced the preceding four years in the Mercy and Marine Hospitals.

Early in 1859 N. S. Davis and a group of the faculty who favored a graded course of instruction resigned and founded what was for a time known as the Medical Department of Land University, afterward as the Chicago Medical College, and later the Medical Department of Northwestern University, Mercy Hospital being used for their clinical teaching.

Fig. 1 Rush Medical College building erected in 1844.

Rush Medical College then announced that in addition to the Marine Hospital they would use the newly opened 200 bed City Hospital for teaching. Following the Civil War the City Hospital was taken over as the Cook County Hospital in 1866.

A course of lectures was inaugurated in the spring and early summer in 1859 by the Rush faculty. In 1860 the College announcement called it the Chicago Summer School of Medicine. This was later called the spring and summer lecture course of Rush Medical College and continued almost without interruption until the regular course was extended to 8 months in 1893. In 1860 the College announced a preliminary course of lectures of 2 weeks in addition to the regular course of 16 weeks.

Daniel Brainard died of Asiatic cholera October 10, 1866 aged 54 years, during an epidemic in Chicago then a city of 200,000. Despite this the College continued without interruption.

In May 1867 the corner stone of an additional building containing an amphitheater with 625 numbered seats was laid and the old structure remodeled at a cost of about \$70,000.00 which was financed by the faculty.

In the spring of 1867 Moses Gunn was invited to the chair of surgery and for 20 years until his death rendered a great service to the institution. In 1867 the requirement of a formal thesis was abandoned and the regular course was increased from 16 to 18 weeks. In 1871 it was increased to 20 weeks.

On October 9, 1871 during the great fire the buildings of the College were burned. There was almost a complete loss from the fire and Rush was left \$65,000 in debt largely to the faculty.

Teaching was continued in a chical amphitheater of the Cook County Hospital and in the dissecting rooms of the Chicago Medical College generously offered to them. The rebuilding was delayed until the permanent location of the new Cook County Hospital could be determined so that the College building could be erected adjacent to it.

During this period a temporary crude brick structure for lecture and dissecting rooms, costing about \$3,000.00 was built on the grounds of the old County Hospital at 18th and Arnold Streets. The College occupied this for 4 years from 1872 to 1876. The corner stone of the building at the present location, the corner of Harrison and Wood Streets, chosen because it was diagonally opposite the new Cook County Hospital was laid November 20 1875. The formal opening took place on October 4, 1876 (Fig 3). The lot and building cost about \$54,000.00. Most of the money was obtained from the faculty and \$11,000.00 from the Central Free Dispensary which occupied the first floor.

From the first use of the Blaney Dispensary Rush has always maintained the importance of clinical teaching. When the first building was erected clinics were held there for the medical and surgical treatment of patients before the students. This dispensary was abandoned with the burning of the building in 1871. The County Hospital

Fig. 3 The corner building of Rush Medical College which was used from 1876 to 1914, when it was replaced by the Rawson Building. Senn Hall in the background is still in use.

clinics were used until the opening of the new building in 1876.

The Central Free Dispensary was organized May 4, 1867, under the title of the Brainard Free Dispensary and was supported at first by private donations, occupying small rooms at 239 W Randolph Street. In 1873 it was united with the Herick Free Dispensary, founded in 1871. The endowment at that time was brought up to \$11,000.00 which in 1875 was lent to Rush for a first mortgage on the lot. The College agreed to provide rooms for the dispensary and to furnish medical service with the privilege of using the patients as teaching material for the students.

While these quarters were changed in June 1902 to Senn Hall and later back to the Rawson Building the clinical teaching in the dispensary has never been interrupted. The dispensary and the affiliation with the Presbyterian and Cook County Hospitals may be called the three principal assets of Rush Medical College. The Presbyterian Hospital was organized and building started in 1883 through the efforts of the faculty and an agreement made so that it could be used for teaching purposes. The staff of the hospital almost without exception has always been composed of members of the faculty of the College.

In 1882 for the first time a preliminary examination required in English, physics, and mathematics was held for those matriculating in Rush unless they were graduates of accredited high schools or their equivalent. This was necessary to qualify for practice in Illinois (1884). At this time instruction in the College began to assume a graded character.

In 1877 the regular course was increased from 20 to 21 weeks.

In 1879 the College urged, but did not require for graduation attendance at the spring and summer terms, in addition to the regular term of at least 2, if not 3 years, with a minimum of 3 years of study as heretofore. The period of study was divided into six terms over 3 years.

In 1887 the College required, in addition to studying medicine at least 3 years, that the minimum of two required courses of lectures for the degree of medicine must not have been delivered in "one twelve-month."

After the death of Moses Gunn in 1887, Charles T. Parke was given the chair of surgery and Arthur Dean Bevan, a graduate of Rush (1883) was elected to the chair of anatomy. In 1888 Nicholas Senn was given the chair of principles of surgery and surgical pathology.

In 1889 the College announced that beginning in 1891 three full courses of lectures, at least 6 months each, would be demanded for graduation.

In 1891 at the death of Charles T. Parkes, Nicholas Senn was given the chair of surgery.

In 1892 the announcement stated that each matriculate, in accordance with the state law must study medicine 4 years and take three courses of lectures of at least 5 months each. The College requirements for graduation were increased to 4 years of study and an attendance at three courses of lectures of 6 months each.

In 1893 the regular course was made to cover 8 months and the spring course was discontinued.

A new laboratory building was dedicated on December 4, 1893, just 50 years after the beginning of the first course of lectures.

In 1894 it was announced that after 1895 four full courses of lectures would be required of 8 months each in graded courses. This requirement was changed to go into effect June 1, 1897. At this time (1897) the College still held preliminary examinations for students who were not graduates of high schools or their equivalent.

The early affiliations of Rush Medical College are only of historical interest, as they created no change in the methods of teaching or indeed affected the College in any noticeable manner.

In the annual announcement for 1862-63 Rush Medical College was recognized as the medical department of the University of Saint Mary's of the Lake, located at the corner of State and Huron Streets. No further notice was ever made.

On May 1, 1875 plans were made for Rush to become a department of the old University of Chicago. Although so described in the announcement of 1874-75 the union was never consummated and the subject was never mentioned again in the meetings of the trustees of the College.

In June, 1887 Rush Medical College became the Medical Department of Lake Forest University but it did not involve any close relations and each retained its own autonomy. This relation was dissolved by mutual consent in April, 1898, and almost immediately the affiliation of the College with the University of Chicago was established. The affiliation of Rush Medical College in June, 1898, marked an epoch in medical education not only in the College but in the history of medicine in America.

By the terms of this affiliation, the College surrendered control of its property to the University which at this time made it clear that it was not its intention for Rush to necessarily become its medical school. The University stated that it proposed to establish its own medical school when funds

became available. Rush adopted as far as possible the general regulations of the University. One of the most satisfactory has been the continuous session, or four quarter arrangement, of the college year. This was established for the session of 1899-1900, when the first 2 years of the medical course was transferred to the University.

The increased requirements led to a falling off of the number of students, the lowest being in 1905-06 when the freshman class numbered about 65. This was a marked contrast to the classes of 200 to 250 which was the rule in the preceding years. Few changes were made in the clinical faculty except to increase it somewhat in numbers.

Since 1914 the requirements have included a fifth year consisting of a hospital internship or of a fellowship in one of the departments.

With the death of Nicholas Senn in 1908 Professor Arthur Dean Bevan succeeded him as head of the department of surgery. In 1934 Dr. Vernon C. David was given the chair of surgery at the retirement of Professor Bevan who had served his Alma Mater as a teacher for 46 years.

In May 1924 a new contract was executed between the Corporation of Rush Medical College and the University of Chicago in accordance with which the affiliation of 1898 was superseded and the University took over the work of the College as a department. This went into effect June 16, 1924. Thereafter only the last two years of clinical work has been offered by Rush Medical College.

With the organization of the School of Medicine of the Division of the Biological Sciences of the University of Chicago the work of the first 2 years of medicine, formerly given in co-operation with Rush, was increased to include the third and fourth clinical years, in the university hospitals and clinics. It was so arranged that the work of the third and fourth years could be taken either on the quadrangles or in Rush Medical College. In 1924 the old college building, used since 1876, was replaced by the Rawson Clinical Laboratory and the Norman Bridge Laboratory of Pathology.

Before the affiliation of Rush with the University there were 525 graduates. To September, 1934, there has been a total of 9,917 graduated from Rush Medical College.

Rush Medical College, through the efforts of its faculty by means of its opportune and successful affiliations with clinics, hospitals, and the University of Chicago and through the discoveries and services of the physicians who have studied there, has achieved immortality. May Rush so continue, as in the past, to signify the best in medicine.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE fourth edition of Blair Bell's most excellent textbook of gynecology¹ has been expanded and enlarged in its scope. Chapters have been added on the history of gynecology on ethics, and on the medicolegal aspects of gynecology. It is gratifying to find a chapter on contraception even though the discussion of this subject leaves much to be desired. The author might well have made this chapter more complete, since reliable information on this subject has not yet found its way into the standard text books.

The chapters on the problems in endocrinology on endometriomata, and on malignancy have been rewritten and brought up to date. Many new illustrations have been added throughout the book. The admirable style in which the previous editions have been written, has been carried over into this edition. This work should continue to be one of the standard English textbooks of gynecology.

RALPH A. REID.

THE fascinating story² by Frederick Watson of the life of Sir Robert Jones, once begun, is difficult to lay down until one has read to the end.

The story tells itself so simply and directly that the reader hardly realizes until he has completed it that this book is beautifully written and a very great credit to the writer's art.

If one could sum up the story of Sir Robert Jones' life in a few words they would be that he was a man loved far above the measure which usually falls to the lot of men. Throughout his life and work that devoted affection of family, associates, friends, patients, and even casual acquaintances, stood out predominantly and furnished the most potent factor in the influence he wielded and the results he was able to achieve in behalf of the causes which moved him so strongly.

Fortunate in his parental background and early home life, he was equally fortunate in the opportunity that came to him at the age of 16 to enter the home of his aunt Elizabeth and her husband, Hugh Owen Thomas. In Watson's words

To live under the same roof with Thomas must have been a daily adventure. His passion for work and his excitement of life did not remove him from his wife and her young nephew. There

were always the evenings or part of them. At the end of a long day's toil he would work on his lute, or play the flute, or discuss in his uncompromising fashion some aspect of life or literature. His range of knowledge upon the most academic subjects was remarkable, and his attitude toward all topics strongly coloured by rationalism.

During these years of Jones' apprenticeship Thomas had an immense practice, and Jones literally grew into the practice of orthopedic surgery and under unusually fortunate conditions.

Between 1870 and 1900, Nelson Street (where Thomas lived) was responsible for the medical supervision of the shipwrights, ironworkers, boiler-makers and dockgate men of Merseyside. The accidents from such employments were continuous and severe. There were still the days of sailing ships, as well as steam, and the old case-books show a steady procession year in and year out of ship's captains, carpenters and seamen of all grades and nations, who had suffered injury at sea or in port. These cases came straight to Nelson Street and were treated there from start to finish to the advantage alike of patient and surgeon; for whereas the former received what was practically specialist attention, the surgeon's gain was the observation of injuries of every kind and at every stage. Thomas never held a hospital appointment. But he was not a loser by that, for although he remained to the end of his life outside the professional camp, he alone was able to treat his cases from start to finish in his surgery and dressing rooms.

and

It was to relieve the terrible distress of these people (of the class) that Thomas opened his free Sunday clinic, where, assisted by a large staff, he laboured from early morning throughout the day. It was at these Sundays that the spectacle of deformed babies and young children first set the mind of Robert Jones upon the problem of crippling diseases.

In 1891 Thomas died, and shortly after Jones moved again from 22, Great George Square, where he had established himself in 1885, to 11, Nelson Street. From that date until 1914 the story is one of almost uninterrupted and joyful work at 11, Nelson Street, at the Royal Southern Hospital, and at Beachchurch, the open air hospital for crippled children founded by Miss Agnes Hunt.

A distinguished American surgeon has written of this period

Mr Jones begins his day after an early breakfast at 7.30 by visiting his patients at their homes or in his private hospitals where they have been placed. About 11 o'clock he returns to his office, where he passes quickly from one patient to another in the various rooms, spending but a moment with each, but setting at once with an almost intuitive instinct upon the nature of the affection and the essential indication for treatment. Small operations, such as tenotomies and mobilization of adherent joints, are often done on the spot, his lively optimism and cheerful tact being in many cases the only anesthetic employed. A dozen cases are started, none are finished, patients crowd the rooms and wait in corridors, everything to the outsider is hopeless confusion, but one thread after another is picked up by the busy master case difficulty after another solved on the spot, order is brought out of chaos, and in an incredibly short space of time each patient had the proper diagnosis and the proper treatment applied.

¹THE PRINCIPLES OF GYNECOLOGY; A TEXT BOOK FOR STUDENTS AND PRACTITIONERS. By William Blair Bell, B.S., M.D. (London), F.R.C.S. (Eng.). F.C.O.G. (Hon.), F.A.C.S. (Hon.), LL.D. (Oxon.). 4th ed. rev. with the assistance of M. M. Detmow, M.D. B.A. (Liverpool), F.R.C.S. (Edn.), M.C.O.G. and Arthur C. H. Bell, M.D., B.S. (London), F.R.C.S. (Eng.), M.C.O.G. Baltimore: Williams Wood & Co., 1934.

²THE LIFE OF SIR ROBERT JONES. By Frederick Watson. Baltimore: Williams Wood & Co. 1934.

and has been instructed about house management and when so call again.

The writer has never seen anything approaching this mastery of the clinical material or of the technical science. This was equally displayed in the work at the Royal Southern Hospital, where Mr. Jones has surgical service. On his regular operating day, Wednesday, his office exceeds twenty operations. On the Wednesday last the writer was present he did twenty-two beginning at 10 a.m. he finished 1 p.m. doing every operation himself but one, which was done by the house surgeon. The operations were done on table which was also used as stretcher, and by having two of these stretchers-tables and its assistants, the operations follow of each other with almost clocklike punctuality. In an average interval of fifteen minutes, and without any appearance of haste. When one considers that this included dressing in most cases and that there are three knee resections, and other operations of equal importance, the performance seems little short of marvellous. All the operations but one were undertaken for the relief of deformity or joint disease.

Here as in the office practice, the striking thing as the clear and quick appreciation of the gist of the matter in hand, and the instant application of the simple and effective remedy. Another striking feature of the work was the hearty and intelligent co-operation of his associates. Mr. Jones has attracted to himself a group of young men of skill and experience, who with each other in their devotion to him, and to the work, and whose team play if I may use the expression is remarkably effective. There is no question by precedence, the right man is always on hand to do the right thing in the right way. The spirit of the place is as fine as the work and personality of the master.

With the trying days of 1914 came Sir Robert Jones great opportunity but opportunity freighted with grief and great responsibility. How well he acquitted himself and how ably he discharged that responsibility cannot be told in a few words. Most American surgeons are familiar with the story and both the older surgeons and those who 20 years ago were too young to appreciate its significance will delight in reading it in Watson's book. It has added still greater lustre to that of the profession in which we are proud to be enrolled. It has been beautifully summarized by an anonymous writer in the *Journal of Bone and Joint Surgery* (vol. 15 page 542).

Behind his genial, smiling countenance, and apparent simplicity, Robert Jones possessed the keenest brain, the most brilliant organizing ability and the tact, the patience, the perseverance and the self-reliance of a diplomat. Never was man faced with greater difficulty or with more serious opposition than he was in the early days of the War when he was entrusted with the establishment of the first military orthopaedic service of this or any other country. He was appointed to the office as Director of Orthopaedics with the rank of Hon. Major General. England's home service began with 200 beds at Alder Hey in Liverpool but within short time the help of many English and American Surgeons was enlisted and 55,000 beds were equipped and staffed with trained orthopaedic surgeons. The brain which had already solved the problems of the cripple in civil life readily adapted itself to the problems of war. Incredible as it may be, the gigantic task was accomplished and complete service established from first and treatment in the field to the last stages of re-education and after-care. In 1916 he continued and completed his military orthopaedic work through his appointment as Hon. Commandant to the Ministry of Pensions. In recognition of his war services, His Majesty conferred upon him the C.B. and later Knighthood, and the United States Army awarded him the Distinguished Service Medal.

After the weary years of war were ended and its tragic aftermath had to some extent been cleared away Sir Robert Jones might well have retired to a life of ease and contemplation of years well spent. He had made "the main principles of Hugh Owen Thomas acceptable to the medical profession," and had

established the specialty of orthopaedic surgery on a firm foundation. Instead of giving up however he plunged into the work that always seemed to crowd upon him more vigorously than ever. The cause of the cripple which had always been so close to his heart, claimed a large share of his attention. To the organization of a national scheme for caring for the physically handicapped and for the prevention of tuberculosis and of rickets—those diseases which contributed so many new recruits to the army of cripples—he devoted that same energy and organizing ability which had accomplished so much for the wounded soldier. The map of England and Wales, dotted with strategically located orthopaedic hospital schools and orthopaedic clinics, tells better than words how successful his efforts were.

While continuing on a larger scale than ever the surgical practice which he had been forced to give up during the war he still found time to edit the *Orthopaedic Surgery of Injuries* which appeared in 1921 and to write in collaboration with Robert Lovett the *Textbook of Orthopaedic Surgery* (1923) which "records for mankind" the principles and teachings which he constantly exemplified in his surgical work.

It seems incredible that in spite of advancing years he could still continue work and play at the strenuous pace that he set for himself but

retirement, advanced old age, an opportunity to take things easily—all these would have been terrible to him. With ebbing strength he surveyed the past and set his eyes on the future. If he could not be in the heart of the battle of life, he shrank from place in the shadow.

In December 1932 after a year of gradually declining strength he began to fall rather rapidly and on January 14, 1933 he "fell quietly asleep."

To have lived a life so fruitful so filled with service to his fellow men, and to have gone to his last resting place loved and mourned by family by associates, by students, by patients—in short by all who knew him—falls only to the lot of a fortunate few. Watson might well have added to his book the beautiful tribute which appeared in the *Journal of Bone and Joint Surgery* (vol. 15 pages 542-543) which begins and closes with the paragraphs

The kindly word, the cheering smile, the twinkling eye, the whole magnetic personality of Sir Robert Jones remain only as memory. The world's greatest orthopaedic surgeon has completed his life's work, quietly as he was born seventy-four years ago at Rhyll on the North Wales coast, just as quietly he died so the early days of this year at little village in Montgomeryshire.

and

Throughout his career he practised in Liverpool, and Liverpool has paid its last and greatest tribute to the loser of one of its citizens. The ashes of Sir Robert Jones are the first to find resting place within the walls of the Cathedral. The urn stands on a column of stone, close to the foundation pillar beneath the stained glass window dedicated to "Service." As long as the walls of that vast cathedral stand, they will shelter all that has died of Robert Jones, as taken and personal of his service to mankind. In the hearts and minds of those who come within the glow of his presence and who learned humbly to love him, his spirit still lives.

SCHWARTZ L. KOCZ.

VOLUMES vii and ix of the twelve volume *Cyclopedia of Medicine* edited by George M. Piersol and Edward L. Bortz are now available (Review of first seven volumes appeared in the December, 1933 issue page 822.) Volume viii continues the alphabetical arrangement of the subjects beginning with the letter 'L' and the first topic is 'Larynx, Disorders of'. This section covers 69 pages and includes infections and nervous disorders together with the tumors of the organs. The section on metabolism is given 151 pages and covers proteins, fats, carbohydrates, and minerals. Myrrh is the last subject appearing in this volume and its pharmacology, preparations, dosage, and therapeutics are discussed briefly. Volume ix begins with the nails and a discussion of their structure, deformities, care, and disorders. A section of 70 pages is given to plastic surgery where technique is described and illustrated quite freely. The subject of pneumonia is well done. A discussion of potassium and its preparation and doses ends this volume. Attention is called to these topics only in that they indicate the general nature of the subject matter treated.

The volumes are 7 by 10 inches and the binding has been changed from the flexible to the conventional stiff type. The material is well arranged and the treatment of the subjects are concise and remarkably complete.

M. HERBERT BARKER.

THE purpose of Dr. Vaughn's monograph of 248 pages is to review the present position of the knowledge of the anemias. She has been assisted by Professor H. M. Turnbull in the description of the pathological anatomy of various anemias. In the first chapter a review of normal erythrocyte measurements and a brief account of the anatomy and physiology of erythropoiesis are presented. The anemias are classified under the general headings of dyshaemopoietic, post haemorrhagic, hemolytic, and unclassified anemias. The anemias of infants and children are included in the classification and in the clinical descriptions. Each individual type of anemia is considered from the standpoint of etiology, symptomatology, diagnosis, and treatment. Abundant reference to the literature is made throughout the text.

Under the grouping of the deficiency dyshaemopoietic anemias, the recent conceptions and literature concerning iron deficiency anemia and anemia due to deficiency of the pernicious anemia factor are presented. The relationship of this group to abnormalities of the gastro-intestinal tract is brought out. Under unexplained dyshaemopoietic anemias, the author includes the less common leuco-erythroblastic anemias. This type of anemia was observed in diseases involving the bones which included

carcinomatosis, myelomatosis, osteosclerosis, and Cooley's anemia. It is suggested that these conditions do not cause anemia by crowding out erythropoietic tissue but rather by depriving the blood cells of food factors necessary for normal ripening. Further under dyshaemopoietic anemia, a description is given of erythroblastosis fetalis which includes hydrops fetalis, icterous gravis neonatorum and congenital anemia of the newborn.

Dr. Vaughn has drawn frequently from her own experience in giving specific details of the findings in various anemias. Characteristic diameters of the erythrocytes are illustrated in the accompanying Price Jones curves. The material in general is presented on the basis of the evidence at hand and there is little if any tendency toward dogmatism. It is of interest that more than half of the articles from the large bibliography appeared after 1929. If hematologic research continues to progress as it has in the past, it is likely that this book will need revision in the near future.

This excellent monograph should be invaluable to the physician or student who wishes to familiarize himself with the revolutionary advances in the knowledge of the anemias that have occurred in the past ten years. It should also serve as a valuable reference book to workers in the field of hematology.

HOWARD L. AIT.

IT is a pleasure to see Wright's *Applied Physiology* of which the first edition is dated 1926 already appearing in its fifth edition. Its remarkable popularity among medical students is due to a number of virtues too often lacking in the medical literature of the past. One of these is utmost conciseness of expression. It would be hard to find in these 604 pages, a single superfluous word. Another is utmost conciseness of expression for every generalization there is a specific instance, stated quantitatively when possible. These features adapt the book exactly to its purpose which is to give an up-to-date summary of those facts of human physiology which have clinical application. It is not a book for a beginner since introductory historical and laboratory technical material is excluded. It is a book for the mature medical student who finds the clinical viewpoint stimulating in his study of physiology. It should also be helpful and interesting to physicians and surgeons who find that even conscientious reading of their journals sometimes fails to give a coherent idea of the present state of the science. Among the subjects which many readers will be particularly glad to have presented in this way and to which special attention has been given in the new edition, are blood groups, nephrosis, edema, the anemias, tissue oxidation, the carotid sinus, ischemic pain, sympathectomy, cholecystokinin, the prolans, parathormone, and the hypothalamus.

CORRESPONDENCE

CONCERNING A REGISTRY OF BRAIN TUMORS

To the Editor: A series of some two thousand tumors of the central nervous system collected by Dr. Harvey Cushing during his period of service at the Johns Hopkins Hospital and the Peter Bent Brigham Hospital has been brought to the Yale School of Medicine and put under the curatorship of the undersigned. It is intended that these elaborately catalogued specimens should so far as possible be made useful to those interested in the subject, and it is hoped that the collection will be added to from many sources.

There are many problems relating to tumor classification and expectancy of life after tumor removal that are as yet unsolved. Hence this series of cases may be of help to those who will encounter rare

tumors that they wish to have identified if possible, and concerning which they may desire information, particularly on the basis of type prognosis.

Anyone who may feel inclined to send specimens for diagnosis or may seek information of other sorts is welcome to do so. The following persons, several of them already familiar with much of the material, have kindly consented to act as an advisory board:

PERCIVAL BAILEY, University of Chicago
F. C. GRANT, University of Pennsylvania
S. C. HARVEY, Yale University
C. J. HENNER, Cornell University
WILDER PENFIELD, McGill University
EUGENE SACHS, Washington University
W. P. VAN WAGENINGEN, University of Rochester
S. B. WOLBAST, Harvard University

LOUIS EISENHART, M.D., New Haven Hospital

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

ATYPICAL GROWTH INDUCED IN CERVICAL EPITHELIUM OF THE MONKEY BY PROLONGED INJECTIONS OF OVARIAN HORMONE COMBINED WITH CHRONIC TRAUMA¹

MILTON D. OVERHOLSER, PH.D. M.D. AND EDGAR ALLEN, PH.D. COLUMBIA, MISSOURI
Department of Anatomy, University of Missouri

THE ovarian follicular hormone has been shown by Allen (1927-1932) and by many others to be a powerful stimulator of epithelial growth in the female genital tract and breast.

Dingemans, Freud de Jongh, and Laqueur (1930) reported the presence of large amounts of the female sex hormone in the blood of cancer patients both male and female. Loewe, Raudenbusch, and Voss (1932) found increased amounts of the sex hormone in cancer tissue from men.

Lathrop and Leo Loeb (1916) found that ovariectomy of female mice markedly decreased the incidence of spontaneous mammary cancer. They said that their results demonstrated experimentally for the first time the significance of an internal secretion for the spontaneous development of cancer and that probably any factor which periodically induced increments in growth energy might be a factor in the development of carcinoma.

Con (1927) reported that ovariectomy of female mice between the ages of 15 and 22 days entirely prevented the occurrence of spontaneous cancer of the breast, while the controls of the same strain showed a mammary cancer incidence of 78.5 per cent.

Murray (1928) by removal of the ovaries at 4 to 6 weeks of age in a cancer strain of rats,

reduced the incidence of mammary cancer from 80 per cent to 17.1 per cent. If the males of this same strain, who never developed mammary cancer, were castrated and a whole ovary of a sister transplanted subcutaneously, then these males developed spontaneous mammary cancer in 7.1 per cent of the cases.

Lacassagne (1932), using 3 young male mice from a strain in which only the females developed spontaneous mammary cancer, found that weekly injections of estrin in oil solution produced cancer of the mammary gland in all three males after 5 to 6 months of treatment.

Cook and Dodds (1933) reported estrus exciting activity to be possessed by the two most potent carcinogenic hydrocarbons yet known.

Zondek (1930) found the ovarian follicle stimulating hormone of the anterior pituitary in the urine of 81.8 per cent of women with genital carcinoma.

Hofbauer (1930) reported that anterior hypophysis transplants and extracts in guinea pigs produced a proliferation of the epithelium of the cervix into the subepithelial tissues which he considered to be a precancerous condition. His anterior pituitary treatment should have increased the production of the follicular hormone, although he interprets his

¹This work has been assisted by a grant from the Committee for Research in Problems of Sex of the National Research Council to Dr. Edgar Allen.

results as direct stimulation of the cervical epithelium by the pituitary hormone. He says: Die Deutung dieser Versuchsergebnisse kann nur so lauten, dass der Hypophysenvorderlappen einen spezifischen stimulierenden Einfluss auf das Deckepithel der Portio vaginalis und zu einem gewissen Grade auf das Zylinderepithel der Cervix ausübt.

These facts led us (Overholser and Allen 1933) to study the changes produced in the cervical epithelium of the monkey by injections of genital growth hormones combined with chronic trauma.

MATERIALS AND METHODS

Nine *Macacus rhesus* monkeys were used. Seven were sexually mature and two immature. None of the animals had ever been pregnant so far as we know although some of them were shipped to us without past histories.

The cervixes were traumatized by scissors cuts through a vaginal speculum. This procedure was repeated at 7 to 10 day intervals throughout the experiment. In addition to the cuts a small metal clip was clamped on the cervix in some of the animals. Subcutaneous

injections of hormone were made twice daily, morning and evening as a rule. The daily dose of estrin (ovarian follicular hormone) given as theelin¹ or amniotin² ranged from 50 to 360 rat units. The theelin preparation used contained 50 rat units per cubic centimeter. Two preparations of amniotin containing 200 and 50 units per cubic centimeter respectively were used. Four animals also received injections of corporin³ (a hormone of the corpus luteum) during the latter part of the estrin injections.

EXPERIMENTS

Monkey 1. This animal had been ovariectomized for some months previous to the experiment and the sexual skin was pale. The vaginal portion of the cervix was cut several times with a pair of scissors and the tissue squeezed tightly with a hemostat. On the following day injections of estrin were begun. In the first 17 days 1,660 rat units were injected.

Vaginal examination on the fourth and seventh days of the injections produced profuse hemorrhage from the cuts in the cervix and no additional trauma was made at these times. On the seventeenth day the sexual skin was red, the cervix appeared nodular and, as there was no bleeding, it was retraumatized. At this time all injections were suspended for 10 days. On the twenty-fourth day the sexual skin was still red, but examination revealed a stenosis of the vagina which prevented visualization of the cervix.

On the twenty-eighth day injections of estrin were begun again and in the following 62 days 3,830 rat units were injected.

Examination on the thirty-first day showed a red sexual skin and a persistence of the vaginal stenosis.

¹Furnished by Parke-Davis and Company for experimental purposes.

²Furnished by E. R. Squibb and Sons for experimental purposes.

³Prepared according to method described by Turner, C. W. and French, A. H. M. *Am. Jour. Exp. Biol. Nat. Sci.* 174, 1932.

Fig. 1. Monkey 1. Section of cervix showing extreme hyperplastic condition of epithelium following estrin injections. $\times 77$.

Fig. 2. Monkey 1. Section of vagina showing definite cornified layer of the epithelium and pigment granules in the basal layer of cells. $\times 300$.

The stenosis was opened up with a knife and the vagina tightly packed with cotton. Seven days later (38th day) it was possible to view the cervix which was re-traumatized at this time the sexual skin was red.

On the forty fifth day a metal clip was clamped on the cervix. Examination 7 days later (52nd day) showed the clip still in place and the sexual skin very red. A week later (59th day) the clip was found loose in the vagina and was replaced on the cervix. The sexual skin was a bright red. Fourteen days later (73rd day) the metal clip was removed and several cuts made in the cervix, thus causing profuse hemorrhage. The clip was reapplied on the eightieth day.

Ninety days after the injections were started the animal was killed. It had been losing weight and strength during the last weeks of the experiment probably as a result of hemorrhage from the cervix. On the day of killing it was extremely emaciated and weak, being unable to rise. During the experiment a total of 5,490 rat units of caetogenic hormone were injected.

Autopsy showed the metal clip still attached to the cervix, which was hypertrophied and nodular. Sections are shown in Figures 1 to 5. Figure 1 shows the extreme hyperplastic condition of the epithelium covering the vaginal portion of the cervix. This is the usual follicular hormone effect (Allen, 1927). Figure 2 is a section of the vagina and shows a definite cornified layer of the epithelium. Pigment granules are also present in the basal layer of cells.

Sections of the cervix taken near the junction of the stratified squamous with the columnar epithelium (Figures 3 and 4) reveal epithelial downgrowth

Fig 4 Monkey 1 Section of cervix showing epithelial downgrowth and overgrowth with epidermization of cervical glands $\times 50$

Fig 3 Monkey 1 Section of cervix showing epithelial downgrowth and overgrowth. Epidermization of cervical glands. Enlarged bulbous rete malpighii $\times 65$

and overgrowth, columnar gland cells being partially or completely surrounded with stratified squamous epithelium. Enlarged bulbous rete malpighii are also seen in Figure 3.

Figure 5 is a high power photograph of glandular epithelium surrounded by many layers of stratified squamous epithelium. As the latter increases in thickness the columnar cells of the gland are separated from their blood supply and degenerate. Nuclear variation is seen in the squamous cells, consisting of differences in size, shape, and staining reaction.

Monkey 2. This animal had been ovariectomized for some months previous to the experiment and the sexual skin was pale. The cervix was traumatized and on the following day injections of estrin were

Fig 5 Monkey 1 Glandular surrounded by stratified squamous epithelium. Variation in size and staining reaction of the nuclei is seen. $\times 340$

Fig 6 Monkey 2. Section of cervix at junction of stratified squamous with glandular epithelium. Epithelial hyperplasia resembling a leucoplakia. $\times 77$

begun. In 17 days 1,660 rat units were given. The injections were then stopped and 3 days later (30th day) the animal was killed.

On the fourth and seventh days the cervix was retraumatized. The actual skin was very red on the seventeenth day when the cervix was again traumatized.

At autopsy the cervix was hypertrophied and irregular. Sections of the cervix are shown in Figures 6 and 7. Figure 6 taken at the junction of the stratified squamous with the glandular epithelium shows a marked epithelial hyperplasia resembling a leucoplakia. Squamous epithelium surrounds columnar cells and there is marked downgrowth and irregularity of the rete malpighii. A round cell infiltration is seen in the connective tissue.

Figure 7 is a high power view from Figure 6. Three glandular tubules of columnar cells are completely surrounded with stratified squamous epithelium.

Monkey 3. This animal was ovariectomized, the sexual skin being moderately red at the time. On the sixth day after ovariectomy the cervix was traumatized and a metal clip clamped on it. Cervical trauma was repeated on the twelfth day, the sexual skin being pale at this time. Injections of estrin were started on the twenty first day, beginning with 40 rat units daily and increasing to 90 rat units daily in 17 days. Eight days after injections were started the sexual skin was red and remained so throughout the experiment. On the sixty ninth day (48 days of injections) the estrin was stopped after 3,047.5 rat units had been given. Fourteen cubic centimeters of corporin were then given in the next 8 days, 800 rat units of estrin being given with it. A total of 4,747.5 rat units of estrogenic hormone were therefore injected during the experiment.

Cervical trauma was repeated on the twenty second, twenty ninth, fortieth, fifty first, sixtieth, sixty eighth and seventy seventh days. The metal

Fig 7 Monkey 2. A high magnification from Figure 6. Three glandular tubules of columnar cells completely surrounded with stratified squamous epithelium. Infection present. $\times 300$

clip remained on the cervix throughout the experiment. Four days after all injections had been stopped (81st day) the animal was killed.

At autopsy the cervix was very nodular and irregular with several necrotic areas. Figures 8 to 10 show sections of the cervix. An ulcerating area was found in which there was marked downgrowth of the epithelium with formation of many isolated epithelial nests (Fig. 8). A high power photograph of this region is shown in Figure 9. The borders of the epithelial masses are irregular with no basement membrane. The nuclei vary in size and shape and are hyperchromatic. A gland like lumen is seen containing a few leucocytes and epithelial cells. Leucocytes are also seen in the connective tissue.

Figure 10 shows an area of epithelial downgrowth and gland overgrowth with atypical epidermization. The columnar cells are undergoing degeneration. This is a duplication of the condition usually diagnosed as a precancerous lesion in human material.

Monkey 4. This animal was ovariectomized, the sexual skin being very red at the time. Injections of estrin were begun 22 days later, starting with 40 rat units daily and increasing to 90 rat units daily in 13 days. After 1,002.5 rat units of estrin had been injected in 15 days it was stopped and 10.7 cubic centimeters of corporin were then injected in the next 8 days. Injections were then discontinued for 35 days, following which 1,800 rat units of estrin were given in 5 days. All injections were then stopped and the animal was killed 33 days later. During the 51 day injection period a total of 3,802.5 rat units of estrogenic hormone and 10.7 cubic centimeters of corporin were injected.

No cervical trauma of any kind was given to this animal.

At autopsy the cervix appeared slightly irregular. Sections showed an extensive area of papillary gland overgrowth, much epidermization and many areas of distinctly atypical epidermoid cells (Figs. 11 and 12). As there was also much infection it is probable that some old cervical injury was present.

Fig. 8. Monkey 3. Section of cervix showing epithelial downgrowth and presence of isolated epithelial nests in an ulcerating area. $\times 50$

Monkey 5 This animal had been ovariectomized several months previous to the beginning of the experiment. The cervix was traumatized and 2 days later injections of estrin were begun and continued for 16 days, when the animal died. A total of 1,535 rat units of estrogenic hormone were injected. The cervix was retraumatized three times during this period.

At autopsy the cervix appeared somewhat nodular and hypertrophied, with several necrotic areas. Sections of the cervix showed a very hyperplastic epithellum indicating that the hormone treatment had been effective. A few areas of columnar epithellum surrounded by stratified squamous epithellum were present but this condition was not developed to such a degree as found in the other experiments that extended over longer periods of time.

Monkey 6 This was a young immature animal the sexual skin being slightly pink. A double ovariectomy was performed and 3 days later the cervix was traumatized, a metal clip being also clamped on it. Cervical trauma was repeated on the eleventh day following the operation, the sexual skin being pale at this time.

On the twentieth day injections of estrin were started, beginning with a daily dose of 40 rat units which was increased to 90 rat units by the seventh day. After 1,125 rat units had been given in 20 days, injections of corporin were begun, 16.5 cubic centimeters being given in the next 30 days. Thirty-two hundred rat units of estrin were injected along with the corpus luteum hormone. Injections were then stopped and the animal killed 12 days later (80th day). A total of 4,312.5 rat units of estrogenic hormone were injected.

Fig. 9. Monkey 3. Higher magnification of Figure 8. Epithelial masses are irregular with no basement membrane. Hyperchromatic nuclei. $\times 250$

The cervix was retraumatized on the twenty-first, twenty-eighth, thirty-ninth, fifty-ninth, and sixty-seventh days. From the thirty-ninth to the fifty-ninth day the clip was not on the cervix. The sexual skin was moderately red after the ninth day of injections and remained so throughout the injection period.

At autopsy the cervix was nodular. Sections showed a sloughing of the superficial epithellum.

Fig. 10. Monkey 3. Section of cervix showing a condition usually diagnosed in women as precancerous. $\times 50$

Fig. 11. Monkey 4. Section of cervix from animal that received hormone injections only. Papillary gland overgrowth, much epidermization and areas of atypical epidermoid cells. $\times 85$.

although in many regions of the cervical canal glandular cells were surrounded by stratified squamous epithelium. A large proportion of the vaginal epithelium had also been sloughed, but intact areas were in a hyperplastic condition, indicating that the hormone treatment had been effective. The sloughing of the epithelium in this animal was no doubt caused by severe infection.

Monkey 7. This was also a young, immature animal, the sexual skin being slightly pink. A double ovariectomy was done and 5 days later the cervix was traumatized, a metal clip being also clamped on it. Cervical trauma was repeated on the eleventh day following the operation.

On the twentieth day injections of estrin were started, beginning with a daily dose of 40 rat units and increasing to 90 rat units in 18 days. Injections were continued for 53 days, a total of 4,267.5 rat units being given. Eight days after the beginning of the estrin injections the sexual skin was slightly swollen. At 35 days it was moderately red and at the end of the 53 days it was extremely red. Twenty-five cubic centimeters of corporin were given in the next 8 days. All injections were then stopped, and the animal killed 43 days later (122nd day). By the sixteenth day after the stopping of all injections the sexual skin was pale and remained so.

Fig. 12. Monkey 4. Higher magnification of Figure 11 showing atypical cells. $\times 205$.

The cervix was retraumatized on the twenty-first, twenty-eighth, thirty-ninth, fiftieth, fifty-ninth, sixty-seventh, seventy-sixth, eightieth, ninety-sixth, and one hundred and thirteenth days. On the ninety-sixth day when the cervix was cut about 2 cubic centimeters of thick pus ran out. On several occasions the clip was found loose in the vagina but was resipped each time.

At autopsy the cervix appeared white and nodular. Sections showed an atrophic sloughing epithelium. The vaginal epithelium was also atrophic. The uterus, removed at the time the injections were stopped, showed a hyperplastic condition of the endometrium. Since this animal was killed 43 days after all injections were stopped, the atrophic condition of the epithelium would be expected. The sloughing was no doubt caused by severe infection.

Monkey 8. This animal was a normal control with both ovaries intact. Cervical trauma only was given—no injections of any kind being made. The cervix was traumatized and a metal clip clamped on it. The trauma was then repeated on the eighth, eighteenth, twenty-fifth, thirty-sixth, forty-seventh, fifty-sixth, sixty-fourth, seventy-third, eightieth, ninety-third, and one hundred and tenth days. The animal was killed on the one hundred and nineteenth day. The metal clip remained on the cervix throughout the experiment. The sexual skin was very red at the beginning of the experiment and remained so, indicating that the ovaries were actively secreting hormone throughout the experiment.

At autopsy the cervix was moderately nodular. Sections showed a few areas of columnar epithelium partially or completely surrounded by stratified squamous.

Monkey 9 This animal was an ovariectomized control. Both ovaries were removed, the cervix traumatized, and a metal clip clamped on it. No injections of any kind were given. Cervical trauma was repeated on the eighth, eighteenth, twenty fifth, thirty sixth, forty-seventh, fifty sixth, sixty fourth, seventy third, and eightieth days. The animal was killed on the eighty-sixth day. The sexual skin was pale throughout the experiment.

Sections of the cervix showed an atrophic epithelium at no place was columnar epithelium either partially or completely surrounded by stratified squamous (Fig 13). Sections of the vagina and uterus also revealed an atrophic epithelium such as would be expected in an ovariectomized animal.

There is no agreement among pathologists who have examined our sections as to the exact significance of the epithelial changes produced in these experiments. In a preliminary publication (Overholser and Allen, 1933) it was stated that conditions resembling early cancer had been produced (Monkeys 3 and 4) based on the opinion of a well known pathologist. It appears that as yet there is no generally accepted definite criterion for the positive diagnosis of very early cervical cancer and that this accounts for the difference of opinion on this subject among pathologists.

The present confusion regarding the diagnosis of the precancerous state of the cervix uteri has been recently reviewed by Freedman (1934). He points out that the exact histological definition and diagnosis is still a matter of personal interpretation. Freedman presents sections of human cervical tissue that show excessive atypical overgrowth of new squamous cells along the walls of cervical glands and ducts that are exactly comparable to the conditions produced in these experiments. (See Figs. 3 to 12.) He calls this condition "carcinoid" in preference to the term "precancerous" and states as follows "The fact that we find it impossible to lay a perfect formula for the precancer stage does not preclude its existence. Study of the histogenesis of cancer would prove that there is such a precursory stage call it by whatever name is desirable. The fact that not all of these carcinoid tissues go on to actual cancer does not detract from their importance in the prevention of cancer, and a guarded attitude should be taken, frequent local examinations with biopsies to ascertain any progress toward malignancy

Fig 13. Monkey 9. Section of cervix from ovariectomized animal receiving only cervical trauma. Junction of stratified squamous epithelium with columnar cells. Atrophic epithelium. X55.

should be undertaken if necessary. This is probably the only way to distinguish those carcinoid conditions that will surely turn to malignancy later."

We have therefore been able to produce experimentally in the monkey a condition that occurs in the human cervix uteri. We believe that the squamous epithelium found around the columnar gland cells has arisen by a metaplasia of the columnar cells. We have not observed mitotic figures in either the columnar or squamous cells. This is probably due to the fact that the tissue was not taken at the particular time when mitosis was occurring.

Dr E. T. Engle, of Columbia University, has also observed areas of squamous cells associated with columnar gland cells in the cervixes of monkeys receiving only estrin (Amnionin in oil) injections.¹ His animals received daily injections for several months and the cervixes were not traumatized.

It should be possible by repeating these experiments and extending them over much longer periods of time to determine experimentally whether the changes in question will or will not develop into cancer in the monkey. Either result would be highly important and experiments are now being carried out with a view to demonstrating this point. To what extent the various experimental factors such as trauma, estrin and corporin respectively are responsible for the results obtained also needs further analysis.

SUMMARY

Atypical epithelial growth in the cervix uteri of 4 ovariectomized monkeys (Monkeys 1 to 4) was experimentally produced. The changes consisted of marked squamous epithelial downgrowth, overgrowth and epidermization of the cervical glands in the region of the junction of the stratified squamous with the columnar epithelium. The treatment these animals received was as follows:

Monkey 1 received 5,490 rat units of estrin in 90 days with repeated cervical trauma.

Monkey 2 received 1,660 rat units of estrin in 20 days with repeated cervical trauma.

Monkey 3 received 4,747.5 rat units of estrin and 14 cubic centimeters of corpus luteum extract in 81 days with repeated cervical trauma.

Monkey 4 received 2,802.5 rat units of estrin and 10.7 cubic centimeters of corpus luteum extract in 84 days. This animal did not receive cervical trauma and the changes were very pronounced (Figs 11 and 12) the epithelial cells being very atypical.

In three monkeys the results were practically negative possibly due to the following reasons: (1) injection period too short (Monkey 5); (2) sloughing of epithelium from severe infection (Monkey 6); (3) sloughing of epithelium from infection and from stopping hormone injections 42 days before sacrificing animal (Monkey 7).

A normal control (Monkey 8) receiving trauma only showed a slight amount of epidermization of cervical glands.

An ovariectomized control (Monkey 9) receiving trauma only was completely negative.

THE ORIGIN OF PILONIDAL SINUS

WITH AN ANALYSIS OF ITS COMPARATIVE ANATOMY AND HISTOGENESIS

S. L. FOX, M.D.¹ BALTIMORE, MARYLAND

Surgical Pathological Laboratory Department of Surgery Johns Hopkins Hospital and University

THIS paper records the results of a study of pilonidal sinuses (also known as sacrococcygeal fistulae) and presents evidence that they are derived by a process of ectodermal invagination.

Contributions to the nature and origin of pilonidal sinuses have been few and are chiefly by investigators on the Continent. Couraud 1883, Stone 1924 (37), and Weinstein 1933 in reviewing the literature found that J. M. Warren was the first to report this lesion. Warren described two cases and believed that the lesion was the result of an alteration of the polarity of growth of the hair follicle which grew inwardly from the surface and pulled "its hole in after it." This idea was purely hypothetical and lacked any embryological basis. Hodges 1880 who gave to the condition the name pilonidal sinus (meaning nest of hair) also advanced a theory that this affliction was due to the ingrowth of hair in the postanal region as the result of unclean habits and erosion of the skin. Wendelstadt, quoted by Stone (37) and Ewing reported a case containing skin and hair, and he believed that the hair acted as a plug causing the retention of infected material in a fistulous tract. Vaughan Gross and others also held to the belief that the anomaly followed interception or inclusion by the integument of surface hair follicles. The earliest writers advised surgical excision for treatment.

THE NEUROGENIC THEORY

At present there are two prevalent theories as to the causation of pilonidal sinus: first, that which traces the origin of the condition to a persistence of coccygeal vestiges of the neural canal and second that which derives the lesion by a process of ectodermal invagination. The adherents of the former theory are in the majority. On the Continent the first to advocate this thesis were Tourneux and Herrmann in 1887. These investigators made sec-

tions through the sacrococcygeal region of human and chick embryos and came to the following conclusions which have been widely read and generally accepted. In young embryos the spinal cord at first extends to the tip of the vertebral column and becomes attached to the skin caudally. At the end of the third month there is a considerable inequality in growth between the medullary tube and vertebral column which results (due to the elongation and downward thrust of the latter) in drawing the spinal cord upward in cephalad direction. The stretched distal portion though still adherent to the skin, and continuous in structure with the rest of the spinal cord (Kunitomo 1) becomes divided into two segments: a "direct" part and a caudal or "reflected" part.² By the fifth month the proximal or "direct" portion has atrophied and disappeared and the "reflected" portion becomes separated from the central nervous system. This vestige becomes converted into a tubular structure lined with columnar or polyhedral epithelial cells to which the authors give the name "coccygeal vestiges of the medullary tube." This structure reaches its maximum development in the fifth month and subsequently undergoes progressive atrophy. Tourneux and Herrmann believed that the failure of these coccygeal medullary vestiges to atrophy was the etiological factor in the formation of congenital sacrococcygeal tumors and sinuses.

The next important contribution on this subject was made by F. B. Mallory in 1892. Mallory in a review of the literature attempts to reconcile the various viewpoints and presents microtome sections of several embryos from 3 to 6 months old. He found rather consistently a tubular structure lined with several layers of columnar or cuboidal epithelial cells lying between the coccyx and the skin in

According to Kunitomo the separation between the main part of the cord and the distal end which eventually forms the filum terminale, takes place at about the level of the thirty-second vertebra.

Fig. Path No. 5806 Photomicrograph of a section through the caudal extremity of a white female, 99 millimeter embryo (4 1/2 weeks). Note the invaginations and the thickened epithelium in this region. The clusters of cells beneath the epidermis later differentiate to form hair follicles and glands.

Fig. 2 Path. No. 5806 Photomicrograph of a section through the same embryo shown in Figure 1 but at a slightly higher level. Note how closely the invaginating process approximates the coccyx. The intervening tubular structure is a portion of the coccygeal vestiges of the primitive neural tube.

the median line. This canal lay in a region studded with glands and hair follicles and where ectodermal invaginations were a common and predominant feature in the development and regression of this portion of the human tail. Mallory also came to the conclusion that the congenital depressions, dermoid cysts and sinuses found in the midline of the sacrococcygeal region arose from the persistence of medullary vestiges of the spinal cord. The clinical finding of hair within the recesses of these sinus tracts was vaguely explained by the presence of neighboring dermoids or the migration of surface hair and foreign accumulations.

Oehlecker in 1926 also investigated these coccygeal vestiges of the neural tube. His conclusions concerning the formation of pilonidal sinuses and cysts were as follows: Due to the rapid growth of the caudal or non-vertebral portion of the cauda the caudal ligament puts traction on the thin hairless areas of skin overlying it in the sacrococcygeal region. This traction is increased as the subcutaneous fat in this area grows and the caudal ligaments simultaneously become shortened.

As a result of this traction the margins of the surrounding skin containing hair follicles are also to some degree invaginated. The skin overlying the rapidly growing vertebrae being unable to keep up with the downgrowth of the vertebral column is displaced posteriorly and upward as is also the tip of the caudal ligament. By the fourth or fifth month the skin which originally covered the tip of the coccyx is drawn upward so as to lie over the third or fourth caudal vertebra and later goes higher. (The point where the caudal ligament radiates into the skin makes a very thin hairless, vascular area which he calls sacral bald spot.) "The normal products of the skin metabolism readily accumulate to form cysts or discharge intermittently as fistulae."

Thus the writer presupposes the coexistence of hairless and hair containing integument in the same region and a special migration upward of neurogenic elements having lost their maternal connections and possessing no fixed point of attachment such as the spinal cord has with the brain at the foramen magnum. If one supposes that the fixation point is the skin then the direction of the pilonidal

Fig. 3 Path. No. 55002. Photomicrograph of a section through the coccygeal region of a white female, 101 millimeter embryo (15 1/4 weeks). The coccygeal medullary vestige is fully developed and lined with columnar epithelium. The ectoderm however is only slightly thickened and its appendages have not yet begun to appear.

sinus should be downward instead of upward which is not the usual clinical finding as shall be explained later.

THE THEORY OF ECTODERMAL INVAGINATION

The earliest proponents of this theory thought that pilonidal sinus was due to a dermoid cyst. Lannellongue is quoted by Mallory as follows: 'After the medullary canal is formed, the mesohlast passes back between the vertebral column and the external epidermis except in the region of the sacrum where little of this tissue is interposed so that this region is reduced to epidermis and bone. Consequently the superficial layer (epiblast) joined at a later period to the mesohlast preserves closer relations with the bone and later when the subcutaneous tissue is developed around these places a depression will be formed. If deep and narrow enough the orifice may close up and a dermoid cyst be the consequence.'

One of the first constructive contributions to the theory of ectodermal invagination as the cause of pilonidal sinus was made by Stone. In his first paper (37) in 1924 he reported 61 cases of which all were white, 16 per cent female and the oldest was 49 years

Fig. 4 Path. No. 55000. Photomicrograph of a section through the coccygeal region of a white female, 132 millimeter embryo (17 1/4 weeks). Note the papillary folds of thickened ectoderm and the numerous clusters of cells in back of the coccyx.

and the youngest 18 years of age. Twenty-five cases had previous operations and some sinuses were of 10 to 20 years' duration. Following a personal communication with Dr. George L. Streeter of the Carnegie Institute of Washington, Baltimore, Maryland, Stone came to the conclusion that the coccygeal medullary vestige, which has no opening communicating with the skin, consists of cells which have become so differentiated that they could not be expected later to give rise to skin even though a cystic remnant should persist and that like the breast and the external ear the pilonidal sinus is due to a special local downgrowth of epithelium originating from the true skin and not from the medullary groove.

In 1931 Stone (38) in another paper upon the subject made the following observations: First that in a few cases there were several congenital orifices, skin lined and lying close together in or near the midline. Second he

Fig. 5 Path \ 580 Photomicrograph of a section through a colored male, 68 millimeter embryo (50½ weeks) in the region of the coccyx. Note the persisting invagination and the developing hair follicles and glands (The medullary vestiges are present, but are not seen in this figure.)

discovered that in many species of birds there is described a preen or oil gland called uropygial gland which lies embedded in the subcutaneous fat over the last caudal vertebra. It consists of numerous straight tubules which converge and empty into a collecting chamber or small cavity which in turn empties through an epithelium lined duct onto the skin of the back. At the mouth of the duct there is often a tuft of fine hair-like feathers. There may be several ducts (1 to 6 in number) and they lie in or near the posterior midline. The gland secretes an oily material which the bird conveys by its beak to stroke on its feathers and the duct is directed in an upward direction like the pilonidal sinus in the human. This view quoted by the author from Lughetti and Schumacher is contended by Paris, who states that these are special scent glands concerned with protection and sexual attraction. According to

Paris, all amniotes, reptiles, and mammals as well as avians, have similar structures which are formed by inward budding invagination of epithelium.

Thus, while a general agreement exists that some vestigial structure or anomaly in the embryo is responsible for the origin of pilonidal cysts its exact nature is a matter of dispute. A re-study of the sacrococcygeal region was therefore undertaken in human embryos to see if some structure could not be identified and more definitely associated with the lesion. Serial sections were made in seven embryos¹ through the caudal extremity from the anus to the region of the sacrum. Grossly in the region just dorsal and cephalad to the anus in a 3½ months fetus, there could be seen with the naked eye and with low power lenses a pattern of grooves and creases which might well be taken for ectodermal invagination. A pit could be demonstrated in the 5½ months old embryo which was much deeper in the older specimens.

The first embryo was a 99 millimeter (14½ weeks) white female specimen. The activity of the invaginating ectoderm was very striking (Fig. 1). The epithelium in this region was markedly thickened and at various points beneath the epidermis clusters of budding epithelium or growth centers, could be seen. These were in the process of differentiating to form hair follicles and glands of the integument, and were particularly active opposite the points of invagination. In Figure 2 which includes a portion of the coccyx the peak of the invaginating process closely approximated the bone. Here also in the midline between the coccyx and the skin there was a tubular structure lined with columnar cells which was a portion of the coccygeal medullary vestiges (primitive neural tube).

This vestigial neural structure was more strikingly demonstrated in Figure 3 which is a section through a 101 millimeter (15½ weeks) white female embryo. Although this specimen was somewhat older than the preceding one there was nevertheless a definite lag in growth and the skin appendages had

¹These embryos were obtained for me through the kindness of Dr. Caspersen to whom I am indebted for his generous assistance and advice. The specimens were given to the laboratory by Dr. George L. Stricker who also kindly co-operated in this study.

Fig. 6 Path. No. 52148 Photomicrograph of a section through the coccygeal region of a white male, 214 millimeter fetus (27½ weeks). The invaginating process is shown directly impinging upon the coccyx, and the skin appendages are very numerous and well developed.

Fig. 7 Path. No. 52148 Photomicrograph of a section through the same fetus shown in Figure 6, but at a slightly higher level. Note the activity of the pilonidal cleft and compare with the fragmented degenerating medullary vestiges.

not yet begun to develop. There was only a suggestion of infolding and thickening of the ectoderm but the neural rests were larger and nearly completely developed. There seemed to be no relationship in these specimens between the development of the medullary vestiges and the process of ectodermal invagination. In the third specimen the skin could be seen in a further stage of differentiation while the neural rests remained practically unchanged. The ectoderm was markedly thickened and thrown into papillary folds, and the skin appendages were beginning to cluster in back of the coccyx (Fig. 4).

The invaginating process persisted at 20½ weeks (Fig. 5) and the hair sheaths with their keratin centers were more prominent. (The medullary vestiges though present are not shown in this figure.) It is evident that ectodermal invagination in this region varies in form and degree with different embryos. In

other words it does not proceed in graded steps in accordance with age in the first few months of embryonal development. However, at 27½ weeks (Fig. 6), or just before viability the invagination increases in depth and impinges directly upon the coccyx and is prominent at this time. The skin appendages are now very numerous and well developed. (The surgical importance of this anatomical relationship will be stressed later.) At this stage the ectodermal layer is twenty-five cells deep in contrast with the adjacent skin which is four to five cells in thickness. The hair follicles are also three to four times as abundant in the region of invagination. The medullary vestiges, however, are fragmented and the epithelium is degenerating (Fig. 7).

At 29½ weeks or after viability the specimen showed only slight evidence of the pilonidal cleft or pit of invaginated ectoderm

Fig 8. Path No 5215. Photomicrograph of a section through the coccygeal region of a white female, 203 millimeter fetus (20 weeks). The pilonidal cleft is shallow and the neural rests are being obliterated by an apparent new growth of fibrous tissue and an ingrowth of blood vessels (Fig 8).

Fig 9. Path No 5252. Photomicrograph of a section through the coccygeal region of a white female, 226 millimeter embryo (26 weeks). Note the epithelial spur and the thickened ectoderm.

This may be due to the lack of development but is very probably due to a recession of the invaginating process. On the other hand the neural rests are being obliterated by an apparent new growth of fibrous tissue and an ingrowth of blood vessels (Fig 8). Curiously one specimen at 26 weeks showed a spur—between two invaginations of the ectoderm on either side (Fig 9). This brings to mind Lawson Tait's reference to the 'human tail' but the resemblance is undoubtedly imaginative. In no specimen were the neural rests found to communicate with the spinal canal although one could follow them through 125 to 400 serial sections, each 7 microns in thickness.

In the chick embryo in the region of the sacrum may be seen an invagination of ectoderm forming the *glande du croupion* (40). This analogy is merely suggested and not stressed. At this writing it is desired only to present evidence that the forerunner of the

pilonidal sinus may be a specialized and transient skin appendage in the human the function and homologues of which in other species are as yet undetermined. Lawson Tait, quoted by many authors, said that the sinus was due to the loss of a caudal appendage (human tail?) but made no mention of a skin appendage.

CLINICAL OBSERVATIONS

The clinical findings corroborate these embryological data and one does not have to presuppose any special excursion of neurogenic elements or escalator migration of ectoderm over the bony coccyx.¹ In the first place pilonidal sinus is undoubtedly a congenital lesion although it becomes clinically evident practically always after the middle of the second decade. Rarely a case has been reported in infants (28, 35).

¹Dr. Bruster states that there is no definite proof of the fact that skin migrates in this fashion over the sacrococcygeal region. *Personal communication*, October, 1933.

The initial symptom usually follows trauma or the transmission of a superficial infection. The patient states that he has noticed "for some time an intermittent staining of his clothes or foul discharges near his rectum." Localized tenderness and pain are common but systemic reactions such as high fever, nausea and vomiting, chill and malaise are rarely found. These have occurred in cases associated with meningitis (see later discussion). Uninfected pilonidal cysts are almost never found in routine examination—in over 70 cases in the present series all show various degrees of inflammation. A physical examination may reveal the sinus in cases in which the symptoms are so mild and the inconvenience so slight that the patient "never bothered about it." The external opening is found usually in the midline in the region of the sacrococcygeal joint. It is smooth, skin lined, and from its mouth there may be seen fine hairs projecting outward. If the lumen is irregular and covered with granulations, it means that there has been previous operative intervention, or that it is an adventitious opening in which case another point of entrance is to be suspected. Several congenital orifices are not uncommon and they may vary in size from a pin point to about 0.5 centimeter in diameter. These cases may be explained by the fact that the pilonidal cyst may communicate with one or more of the ectodermal invaginations (Fig. 2). Signs of inflammation such as swelling, redness, induration and tenderness may be present and one may express drops of thin, dirty foul pus upon exerting pressure over the tract. When probed the sinuses vary in length and depth and may reach the bone beneath. The direction is usually upward which is a differential point in distinguishing the lesion from fistula in ano, which is directed downward.

Superficial hair follicle abscesses and deep suppurations of bone with severe systemic reactions can be easily ruled out. Venereal tuberculous and neoplastic lesions of the bony parts, of the anus or rectum may be readily dismissed by rectal or sigmoidoscopic examination and by the fact that pilonidal sinus is essentially a benign lesion with benign symptoms. Likewise malignant infections like

Fig. 10. Sacrococcygeal neuro-epithelioma (glioma) (from Rousay et Oberling, *Atlas de Cancer*, Aug. 1931). The upper figure consists of cylindrical-cuboidal cells which line vascular spaces containing red blood corpuscles. In the lower figure the cells are stratified and possess fibrillary extensions. These bundles represent neuroblastic differentiation in the tumor tissue.

anthrax and actinomycosis and deep burrowing fistulous tracts may be ruled out.

The treatment of pilonidal sinuses is not within the scope of this paper, numerous recent articles have covered this phase of the subject.¹ The essential principle is block dissection with drainage, with or without partial primary suture. Location of adventitious branches is facilitated by the injection of the sinus tract with a mixture of methylene blue and hydrogen peroxide in equal parts (Stone 38).

PATHOLOGY

The pathology is best illustrated by describing a case of a medical student 27 years of age who was recently operated upon by Dr. Stone. The specimen when received was 12

Nelson's Surgery, 20; Lewis's Surgery 21; Lacey 10; Moore, 271; Byrne, 3; Cattell and Seifer 7; Dulligan, 10; Landman, 10; Beckman 21; Weinstein, 44; Cole, 8; Mason, 27. Dr. Stone uses hydrogen peroxide to destroy the adventitious tracts (personal communication).

FIG. 1. Path. No. 844. Photomicrograph of a sacral teratoma in a white female infant (age 1 day). It consists of numerous glands embedded in a delicate stroma of connective tissue. There are also adult and fetal cartilage, intestinal and bronchial epithelium, liver, brain, and neuroblastic tissue. A topey performed.

by 2½ by 2 centimeters. In the center was a large bifurcated opening leading into a tubulous tract which tunneled the entire specimen. At each end was an opening, one of which entered the main tract and the other led into a blind pouch of its own. These drainage points were irregular and surrounded by granulation tissue and obviously secondary in nature.¹ There were however two additional congenital lumens with smooth surfaces, and each leading like a flask into a sac filled with hair and possessing a gelatinous lining. The hair was fine, silky and lighter in color than the body hair. The main tract was lined with a velvety thin mucoid substance and contained long dark thick hairs. There was no frank pus and there were no hairs growing from the walls of the sinuses leading to the skin.

¹ Patient had previous operation for pilonidal sinus at which two adventitious tracts were missed.

FIG. 2. Path. No. 57574. Photomicrograph of a choroid in a white female 61 years old. The tumor consists of large, round, vacuolated, hyperchromatic cells growing in a syncytial fashion and strongly resembling hyaline cartilage. The patient died with recurrence.

Histologically the picture of this and other cases is essentially the same. Usually the main tract consists of granulation tissue rich in blood vessels and exudate of a subacute inflammatory nature. There are some polymorphonuclear leucocytes, giant cells, and deposits of blood pigment but predominating are large numbers of wandering cells—plasma cells, monocytes and lymphocytes. Lying loosely in the stroma are numerous hairs without sheaths surrounded by giant cells. This is a very characteristic finding. Elsewhere one finds fully developed hair follicles and sweat glands. The adventitious branches are lined with stratified squamous epithelium like skin but nowhere does one see the characteristic circumscribed structure of a dermoid. In fact, I have never seen a pilonidal sinus contain the cheesy substance or the compressed epithelial lining and keratin

center of an epidermoid or subepithelial dermoid cyst.

INCIDENCE AND POSTOPERATIVE RECURRENCES

Recurrences in cases of pilonidal sinuses are not uncommon. Most of them are due to the lack of understanding of the embryology and pathology of the disease with the result that incision and drainage is performed which is obviously inadequate. Stone¹ believes that recurrences should not exceed 5 to 8 per cent in good hands.

Cattell and Stoller from the Lahey Clinic report 59 cases with 9 recurrences in 40 traced cases. Six of these were cured by second operation. Landsman states that there are about 20 per cent recurrences in infection of the sacrococcygeal region. Stone (37) reported 61 cases from the Johns Hopkins records and private practice of which there were 25 recurrences. One patient had 8 or 10 previous operations. Dulligan reports 25 cases in 25,000 admissions at St. Mary's Hospital, Brooklyn, N. Y. It was his opinion that sacrococcygeal cysts were the result of congenital invagination of ectoderm with all its appendages, which if complete formed a cyst, and if incomplete formed a sinus or fossa. Masson reported 81 cases from the Mayo Clinic, during a 5 year period, of which 25 had multiple openings but he does not state how many were recurrences. (Fifteen per cent in this series were females and the age group ranged from 16 to 57 years. There was 1 case in an infant of 19 months but this was not described.) Masson states that trauma was a frequent finding in the history of these patients. Weinstein reported 13 cases, 85 per cent males and ranging from 17 to 39 years.

Weeder, in a recent article, states that 25 to 35 per cent recurrence occurs in the best hands. This figure is probably too high for present day methods of treatment. This writer believes that if the theory of simple ectodermal invagination were true then all pilonidal sinuses should be cured by the first operation. But this is not as simple as it seems because there may be numerous congenital or adventitious tracts leading from the cyst the entrance of which may be at the

time closed off to any injection of methylene blue and which may be missed with the naked eye. Weeder believes that recurrences are due to the inclusion within the sacrococcygeal junction of a part of the cyst, derived from the unobliterated portion of the medullary canal, during the process of fusion of the dorsal arches which may or may not be complete (spina bifida occulta). He noted that when he injected these cases with methylene blue the surface of the joint and occasionally even the deeper structures were discolored. In these cases, therefore, he recommends excision of the coccyx and curettage of the sacral stump. This procedure was performed in 4 cases, yet in none of these was there any mention of finding grossly or microscopically, any inclusion cysts or cyst walls within the bony parts. We have had the opportunity to carry out Weeder's suggestion in only 1 case since his article was published (case described under "Pathology"). Sections through all the coccygeal joints revealed normal bone and joint structures. There was no evidence of inflammation or tumor or cyst inclusion. However, scattered along the sides of the coccyx were seen minute round vascular bodies like paraganglia consisting of polyhedral cells with densely staining nuclei surrounding blood spaces. These, of course, should not be confused with neural rests the epithelium of which is cuboidal or cylindrical and occasionally ciliated. Grossly there was no evidence of invasion of the sinus tracts into the bony parts. Undoubtedly the discoloration of the joint, or of periosteal or ligamentous structures, when found is due to the trauma of a previous operation or damage by bacterial or chemical agents. Also if Weeder's theory were true a large percentage of the primary and all the recurrent cases should never have been cured.

However, in this connection it should be stated that occasionally the sinus tract leads down to the coccyx (as was shown in Figure 6). In these instances the coccyx should be thoroughly trimmed of its periosteal and fibrous covering. If the deeper structures are involved especially in recurrent cases in which a periosteal reaction may have been already set up, it may be safe and wise to

¹ Personal communication.

excise the coccyx. However the danger of a low grade osteomyelitis complicating such a procedure was pointed out by Stone¹ following his case previously described. For this reason and also because in many cases the sinus is very superficial and may be limited to the level of the sacrum it is felt that removal of the coccyx except in a few instances is not indicated.

A REVISED CLASSIFICATION OF CONGENITAL SACROCOCCYGEAL TUMORS

It is apparent that a different classification of tumors must be made on the basis of the embryological and histogenic character of the structures found in this region (Table I)

TABLE I—SACROCOCCYGEAL NEOPLASMS

	Tissue	Structure	Tumor
A.	Ectoderm	Epidermis	Pilonidal sinus dermoid cyst
B.	Neuroectoderm	Medullary vestiges Meninges	Solid neoplasms— epithelioma, Cr- to-adenocarcinoma Meningioma
C.	Ectoderm	Perianal pit	Keratinous cyst, an- terior cyst, dermoid cyst, Glucosarcoma
D.	Mesenchyme	Knotchard	Chondroma
E.	Undifferentiated tissue A-B-C-D	Tail vestiges	Teratomas

1 *Pilonidal cysts* The pilonidal cyst is a congenital lesion due to a process of normal ectodermal invagination in the embryo which usually disappears but in these cases has persisted in adult life. It commonly contains fine, silky light colored hair and mucoid or gelatinous material is almost always infected and its walls consist of several layers of epithelial cells with glands and hair follicles. Derived from budding or growth centers in the basal layer of the ectoderm which give rise to hair follicles and glands, it consists of cells which form only hair and glandular appendages. For this reason one never sees teratomata, neurogenic growths, or heterologous tumors in pilonidal sinuses. The lesion becomes evident after the middle of the second decade and is probably associated with the development of secondary sex changes concomitant with puberty

Personal communication.

2 *Coccygeal medullary vestiges* F B Mallory (26) reported a glioma originating in the subcutaneous tissues over the coccyx, in a female age 44 years, which metastasized to both groins. Histologically it consisted of small alveoli lined with epithelial cells embedded in a fairly abundant connective tissue stroma. Mallory by differential stain demonstrated coarse, wavy fibrils between cells which filled the alveoli which were unlike connective tissue or smooth muscle fibrils. The tumor in the lymph nodes showed a papillary structure. Undoubtedly this was a neuro-epithelioma, and probably arose from the neural rests which he and Herrmann and Tonneux described. Mallory believed that it had the same origin as the pilonidal sinus.

Fowler described a huge cyst over the sacrum of a 2 months old female associated with bony defects of the sacrum and coccyx. The cyst repeatedly refilled following aspiration. Operation revealed no communication with the spinal canal but this might have easily been missed. The cyst was lined with ciliated cylindrical epithelial cells and was multilocular in character. The tumor was probably derived from a medullary rest of the primitive neural tube its lining being similar to that of the neural canal in early embryonic life. Tumors of this type have no connection with pilonidal cysts.

Law in reviewing the literature on pelvic tumors with sacral attachment, found only 30 cases and added a case of his own—a neuroblastoma in a female, age 27 years.

The coccygeal medullary vestiges may thus in rare instances give rise to large multilocular cystic or solid growths usually on the posterior surface of the sacrum and coccyx (Fig 10). They may present anteriorly if the tumor is large or has invaded the pelvis. The large cystic masses nearly always occur in the newly born or young infant.

3 *Herniation of the cul-de-sac of the terminal meninges* Meningocele presents very little diagnostic difficulty but the association of pilonidal sinus in cases of spina bifida complicated by meningitis has been used by certain writers to support the neurogenic theory.

Rupley and Thompson reported a case of pilonidal sinus with spina bifida in a 336

months old infant. The patient developed meningitis and died. Examination revealed a sacrococcygeal dermoid. The writers believed that the sinus arose from the vestiges of the neural tube. Moise reported a case of a male 18 years of age who was admitted to the New Haven Hospital with headache and pain in the back. He had always had a sinus in the lower lumbar region of the back associated with an intermittent discharge of water fluid. Examination revealed a *Staphylococcus albus* meningitis with spina bifida occulta. Sacral laminectomy was done and effective drainage instituted. The patient survived and was discharged living and well. The author claims that the discharge was probably cerebrospinal fluid and that the sinus led into the dura but his evidence is circumstantial and inconclusive. The meningitis can easily be explained by the lack of bony protection and by either the direct, lymphatic or metastatic extension of the infection particularly in cases of cystic spina bifida where the expanded subarachnoid space lies close to the skin (18). Moore has even reported a proved case of pilonidal sinus containing cerebrospinal fluid, one in which the sinus showed a direct communication with the spinal canal.

4 *Postanal gut and neurenteric canal* Certain anococcygeal tumors and cysts are said to arise from the remnants of the postanal gut and the neurenteric canal. In the early embryo the central canal of the spinal cord and the alimentary canal are continuous around the caudal extremity of the notochord (4). By this union is formed the neurenteric canal which subsequently atrophies and forms a fibrous cord. Hansmann and Ewing cite several cases of tumors containing intestinal wall and portions of nervous tissue which arose from these rests.

The postanal gut is formed as the result of the union of the invaginating portion of the proctodeum, or primitive anus with the intestine at a point anterior to the neurenteric canal. Thus a segment of intestine is left behind which atrophies and disappears. Occasionally in the newly born or young infants a vestigial structure remains which gives rise to cystic tumors situated anterior to the sacrum or coccyx. These tumors were formerly called

"congenital cystic sarcoma." They are composed of closed vesicles lined with glandular epithelium and contain ropy mucus, or glue like fluid (4). The epithelium consists of columnar and goblet cells and one of the essential features for diagnosis is that the cysts have no serous or muscle coats (32). Middeldorpf¹ is said to have been the first to recognize a tumor of this character. Ballantyne reviewed the literature on these tumors and added a case of carcinoma of postanal intestine in a female, aged 38 years. He found only 4 other cases reported. Huge dermoids and teratoma attached to the rectum or sacrum have been described (11, Fig 11, 4, 17, 27).

Tumors of this group are usually single and always occur anterior to the coccyx and sacrum, may be confused with neurogenic growths, but have nothing in common with pilonidal cysts.

5 *Coccygeal gland* The coccygeal gland was originally described by Luschka in 1860. It was first thought to be a single body in front of the apex of the coccyx about 2.5 centimeters in size. In Quain's *Anatomy* the following histological description is given. It consists of masses irregular in shape and size which are very vascular, the vessels having a sinusoidal character. The cells of the gland come into close relationship to the anuses with only a layer of endothelium between, indeed, the presence of this layer is not always easy of detection. Numerous nerves pass to the coccygeal gland and Luschka described ganglion cells within it, but this description has not been confirmed by modern investigation. Jacobson² believes that the mode of development and function of the coccygeal gland are probably connected with that of the sympathetic nervous system.

However (as was shown in Dr Stone's case) the coccygeal gland is only one of a number of paraganglia which are present in this region and which may give rise to paraganglionic tumors. J. Crawford Burns described a case of what he thought was a coccygeal body tumor. It was in a male, 22 years who had a hard fixed mass in the sacrum the size of a fetal head and unattached to the rectum. The

¹ Arch. f. path. Anat., etc., 10:1: 27

² Arch. f. mikr. Anat., 1899, vol. 52.

specimen which was removed at operation consisted histologically of polyhedral cells and numerous blood vessels. The cells were arranged in masses of irregular columns of a malignant nature. The growth subsequently recurred with large pelvic masses and was inoperable. Of course, one should not confuse these tumors which rarely metastasize with sacrococcygeal neuro-epithelioma which are of high malignancy. On the other hand coccygeal paraganglioma should not be ruled out, as has been done (2) on account of finding a normal so called Luschka's gland because

Luschka's gland may be represented by a number of paraganglia in the coccygeal region a fact which is not generally recognized.

6 *Chordoma*. These tumors are mentioned merely because they occur in the sacrococcygeal region and may be confused with the other groups. Their structure resembles hyaline cartilage and mucin may be present. They may grow in an alveolar fashion and must be differentiated from myxochondroma and colloid carcinoma of the intestinal canal (Ewing—Fig 13). Fried and Stone described a case of chordoma which was treated for 9 years for a fistula in ano, perirectal abscess, etc., and the true condition was not discovered until the case came under their observation and microscopic section had been made (Rankin, Bergen and Buie).

SUMMARY AND CONCLUSION

Evidence is presented from studies on the human embryo which indicate

1 That pilonidal sinus is a derivative of skin ectoderm and not neurogenic or enteric in origin.

2 That the structures forming the sinus are derived by a process of ectodermal invagination from the skin surface at the time and in the cells destined to form skin appendages (hair and glands) during the third and fourth months of embryonic life.

3 That its mode of origin and the analogy drawn between this structure and the special 'scent' gland in the sacrococcygeal region of birds and amniotes suggest the probability that the sinus represents a vestigial skin appendage developing at puberty—hence the age distribution of pilonidal sinuses.

4 That coccygeal medullary vestiges exist is not denied but they do not give rise to the pilonidal sinus. They probably give rise to the large cystic and solid tumors which occur usually in infants and the newly born. There is also the possibility that they may play a rôle in the upward direction which the pilonidal sinus takes.

5 Clinical and pathological findings are presented which are satisfactorily explained by this theory.

6 Other congenital growths of the sacrococcygeal region are described because of the sinuses and fistulae which these structures have produced—to clarify some of the confusion which has surrounded the history of their development. In this connection it is suggested that the coccygeal region may possess several sites for the origin of paraganglioma instead of only Luschka's gland as originally thought.

7 It is felt that recurrence following operation for pilonidal sinuses should take place in less than 10 per cent of the cases and is due to the fact that certain of the ramifications are left behind. Furthermore since the coccyx is fully developed in the first 6 weeks of fetal life and has no dorsal arches, and since the fourth and fifth sacral vertebrae have only vestiges of the neural arch it is quite illogical to assume that the coccygeal medullary vestiges may be included within the sacrococcygeal joint. It is my belief that in operations for pilonidal sinus wherein the coccyx is removed and the sacral stump curetted the improvement which is described is not due to the excision of included coccygeal medullary vestiges but due to the removal of the contiguous infection of periosteal or bony parts. One case is reported in which such an operation has been performed and in which no pathological changes could be demonstrated. Low grade osteomyelitis complicating such a procedure should be borne in mind.

8 In the prevention of recurrences it is suggested that wherever the sinus tract extends to the bony parts, the periosteal and fibrous layers should be carefully stripped off and curetted. Dead spaces and recesses with inflammatory products should be guarded against by preventing too early epithelial bridging of the wound and by careful packing.

FUNCTION OF THE LONG PLANTAR MUSCLES

THEODORE A. WILLIS, A.M., M.D. F.A.C.S., CLEVELAND, OHIO

From the Department of Anatomy, Western Reserve University

THOUGH 'the foot functions as a whole and the interactions of the several muscles form a complete unit which must be studied in its entirety' as stated by Hallisy accident and disease tend to concentrate on individual muscles, and to correct the ill effects of these agents intelligently the clinician must have an understanding of the manner in which individual muscles function. Medical literature yields very little exact information concerning the function of those muscles commonly referred to as the long plantar muscles. This dearth of detail is apparently due to the tendency of medical writers to consider the foot as the movable terminus of a fixed leg rather than in its more important function as a fixed base for support and propulsion of the body as a whole.

For example standard textbooks, such as those of Gray, Cunningham, Pierson and Spalteholz give the function of the tibialis posterior as extension, inversion and adduction of the foot. Special studies of the motor system by Lovett, Wright, Mackenzie and others go little if any further into the subject. In German literature one finds a large amount of detailed and exhaustive investigation particularly in respect to muscle weight, cross section area, volume etc. with considerable attention paid to these muscles in their relation to flat foot, but again adequate practical discussion is lacking.

Schlepe, in discussing flat foot due to traumatic section of the tibialis posterior tendon attributes a primary rôle in sustaining the arch of the foot to this muscle. He finds that Hoffa, Schultz, Franke, and Frank support this contention but that Lorenz and others deny it. That Nicolodoni finds this muscle important but not fundamental while Biesalski, Flick, and Mayer ascribe the same function and nearly equal importance in preservation of the arch, to this muscle and the flexor digitorum longus.

Meng, basing his argument on Weber's evaluation of muscle work from its mass, found by

cross sections of the long plantar muscles that in flat feet the flexor hallucis longus is one third weaker than in normal feet though the other muscles are practically unchanged. He regarded the flattening of the arch as the result of the weakness of this muscle and treated the deformity by shortening its tendon. Since a stretched muscle undergoes atrophy it is possible that Meng has confused cause and effect.

A muscle functions by contracting in length to approximate its points of origin and insertion. Either end may act as a fixed point toward which the other is drawn, or in regard to which it is stabilized. In general, muscle pull is exerted in a straight line between two points of attachment. In the muscles under discussion direction of force is changed approximately 90 degrees by arrangement of bones and ligaments comparable to pulleys. Force is then exerted not only at the origin and insertion of the muscle but upon the pulley which tends to move according to the law of component and resultant forces.

The origins and insertions of the long plantar muscles have been sufficiently described by many anatomists. The relation of their tendons to the pulleys, and the rôles of the pulleys themselves in maintaining foot posture have been largely ignored. The present purpose is a review of these details in relation to the preservation of foot posture.

The tibialis posterior has a large origin from the upper central area of the back of the leg. Its principal insertion is into the medial and plantar aspects of the navicular tubercle. Other strong fasciculi are inserted into the medioplantar portions of the metatarsal bases and into the tarsal bones anterior to the calcaneus and talus. Its tendon grooves the back of the medial malleolus and, under the tough ligamentum laciniatum, is separated from the medial surface of the neck of the talus by a thick fibrous pad. Its strongest insertion is into the tubercle of the navicular below and medial to the talonavicular joint.

Other fasciculi extend under the head of the talus to the anterolateral tarsal area. Contraction of this muscle approximates the navicular tubercle to the medial malleolus, inverting and plantarflexing the anterior segments of the tarsus on the posterior. When the ball of the foot is fixed in weight bearing, the same force lifts the head of the talus upward and outward, at the same time forcing the malleolus forward. The arch sustaining power of the tibialis posterior is exerted primarily on the medial malleolus and navicular. The navicular rotates about an axis in the neck of the talus. The same force that inverts the navicular by traction on its tubercle will, when this bone is the more firmly fixed, evert the head of the talus, a motion abetted by forward movement of the internal malleolus (Fig 1).

The writer is at loss for a term to describe accurately the motion occurring in the talonavicular and calcaneocuboid articulations. Together these joints comprise the transverse tarsal articulation. The talonavicular is a shallow ball and socket joint allowing motion in all directions but its mobility is greatly restricted by the almost fixed calcaneocuboid relation. In this discussion the term inversion is used to denote that combination of medial motion of the foot with adduction of the anterior tarsus and rotation upward and outward of the talus head at the talonavicular joint.

The flexor digitorum longus arises from the middle three-fifths of the inner portion of the back of the tibia and is inserted into the four outer toes. Its tendon crosses the articular line of the tibia lateral to the base of the malleolus and makes its turn in a strong ligamentous tunnel on the inner surface of the talus behind below and lateral to the tibialis posterior. It lies medial to the sustentaculum tali, passes under the outer half of the talonavicular articulation and beneath the joint between the second and third cuneiforms. In the sole it receives a reinforcement from the flexor hallucis longus which crosses above it. Its function is given as flexion of the toes, plantar flexion and inversion of the foot. With the ball of the foot fixed in weight bearing, it lifts the talus and adjacent tarsal bones upward and forward. Because its tunnel is

Fig. 1 In this and the following illustrations made from tracings of X rays of the foot in medial, lateral, and dorso-plantar views, with the tendons marked by wires, T marks the turn of the tendon about a pulley. The lines AT and PT represent equal forces anterior and posterior to the pulley and RT the resultant force exerted on the pulley. The force actually applied to the pulley is a combination of the forces shown in the two views. It cannot be accurately represented in a two dimension figure. The tibialis posterior. When the foot is fixed in weight bearing this tendon forces the inner malleolus forward, and lifts the head of the talus upward and outward. Loss of its support allows the malleolus to move backward the talus and navicular to rotate downward and inward, and the foot to evert, particularly at the talonavicular joint.

medial to the subtalar talocalcaneal articulations and its tendon extends laterally to the outer toes, it also forces the talus outward on the calcaneus. Its power is expended primarily on the talus (Fig 2).

The flexor hallucis longus arises from the lower and outer portion of the back of the leg and is inserted into the base of the terminal phalanx of the great toe. Its tendon, well away from the malleolus, traverses the groove on the posterior margin of the talus and is bound tightly in a fibrous tunnel on the medial surface of the calcaneus a half inch behind and lateral to the flexor digitorum. It runs under the sustentaculum tali, the middle third of the talonavicular joint, crosses above the flexor digitorum longus to which it gives a slip and extends under the first metatarsal parallel to the inner border of the foot. Its

Fig. 2 The flexor digitorum longus exerts an upward and outward lift on the talus and calcaneus. Loss of its function allows the foot to evert at the subtalar articulations and the longitudinal arch to sag.

Fig. 3 The flexor hallucis longus, when the ball of the foot is fixed, forces the talus forward and upward, and lifts the anterior part of the calcaneus upward. The tendon turns first in a notch on the posterior margin of the talus, then under the sustentaculum tali. Loss of its support allows depression of the midtarsus, and eversion at the talocalcaneal joints.

function is given as flexion of the great toe and plantar flexion of the ankle joint. In weight bearing its contraction lifts the anterior part of the calcaneus upward forward and outward elevating the arch and inverting the foot. Its arch elevating power is exerted on the calcaneus (Fig. 3).

The peroneus longus arises in the outer and upper part of the back of the leg and is inserted into the first cuneiform and the base of the first metatarsal. Its tendon turns behind the lateral malleolus, crosses the lateral surface of the calcaneus and base of the cuboid and extends diagonally across the sole under the cuboid and two outer cuneiforms. Under the cuboid it lies in a deep tunnel formed by the tuberosity of that bone and strong ligaments. Its function is commonly given as eversion and plantar flexion of the foot. With the foot fixed it presses the lateral malleolus forward and lifts the cuboid upward, inward and, by relation of its tendon to the anterior surface of the tuberosity backward thus supporting the outer border of the arch and with the cross insertion of the fibularis posterior consolidating the transverse tarsal arch (Fig. 4).

The peroneus brevis extends from the outer and lower leg area to the base of the fifth

metatarsal. Its tendon is in direct relation to the lateral malleolus and, particularly when the foot is inverted, makes contact with the calcaneus and cuboid. Its contraction approximates the lateral malleolus and the fifth metatarsal base. It is not actually a plantar muscle, and has little function in weight bearing except in stabilizing the leg laterally. With the metatarsal fixed this tendon exerts a definite forward and lateral force on the fibular malleolus (Fig. 5).

To compare the rôles of these several muscles in actual weight bearing with the foregoing conclusions drawn from a study of their physical relationships a simple apparatus which may be described as follows was arranged. An ordinary bathroom scale was set upon a base board. A foot and leg from which all soft tissues except the long muscles and the ligaments had been removed was set upright on the scale. A small wooden block was placed on the upper end of the tibia, and on this another block with a nut on its under surface through which a bolt was screwed to impinge on the first block. The upper block was attached with wires to the base board. By

Fig. 4. The peroneus longus turns first behind the outer malleolus, which it forces forward, then about the cuboid which it lifts upward, inward and slightly backward. Loss of its function lowers the outer border of the foot and allows the foot to invert easily.

screwing the bolt down any desired pressure was registered on the scale. Strong sutures were placed in the tendons of each muscle and other sutures in the muscles near their origins. Muscle tissue between the two sets of sutures was replaced by elastic bands tension upon which was easily varied by adjusting the suture ties (Fig. 6).

It was found that in dissecting room material the arches of the foot could not be completely depressed without application of force sufficient to rupture the hardened structures. Therefore the plantar ligaments between each two bones were cut relegating support of the arches to the long muscles alone. In this condition the weight of the leg was enough to flatten the arches.

Since little is known as to the actual force exerted by individual muscles in preserving normal foot posture an arbitrary amount of 5 pounds was applied to each of the muscles under discussion. It was applied by interposing stretched rubber bands between the tendons and bellies of the muscles. By test

Fig. 5. The peroneus brevis is primarily a lateral stabilizer of the foot. It exerts a forward and lateral force on the outer malleolus and elevates the base of the fifth metatarsal.

with a spring balance it was found that the rubber bands used were of constant elasticity, and that when 5 pounds traction was applied to any doubled band the band attained a length of 3 inches. Pulls were then exerted on the individual tendons by tightening the anchoring sutures until the interposed doubled bands were stretched to that length.

Experiment 1 An elastic pull of 5 pounds each was applied to the tendons of the tibialis posterior, flexor digitorum longus, flexor hallucis longus, and the peronei longus and brevis. These produced plantar flexion of such an extent that weight bearing pressure could not be applied through the tibia to the foot. Similar pulls were therefore applied to the tibialis anterior and the extensor longus digitorum. These held the leg at a right angle with the foot. The limb was then arranged in the apparatus as described, and subjected to weight bearing stress by screwing down the adjusting bolt. As pressure was increased the talonavicular and calcaneocuboid articulations gave way. The latter was completely depressed to the scale floor at 17 pounds the former at 55. When pressure was again reduced the arches were restored.

Fig. 6. Photograph of the apparatus used in Experiments and 2, showing a leg and foot under adjustable weight bearing pressure. All plantar structures, except the tendons under discussion, have been removed, and all ligaments cut. The arch is sustained by the rubber bands which replace the muscle bellies, under pressure of 40 pounds.

Rotation of the leg forward on the ankle joint elongated the posterior bands while those of the anterior muscle group shortened. The added stress on the anterior portion of the arch from forward shifting of the weight was thus compensated by increased tension on the posterior tendons. In backward rotation of the leg the anterior bands stretched and the posterior shortened. Tonus of these rubber muscles thus adjusted itself to the varying stresses consequent upon the changing positions of weight bearing.

There is, of course, no reason to assume that the different muscles exert an equal force in preserving foot posture. The great amount of work done in determining cross section volume mass and unit work values of muscles is of little practical importance as each of these muscles works under a different arrangement of pulleys and levers, so that a weaker muscle may actually accomplish more than a stronger one. Until the factor of leverages is added to the existing complicated tables of weights and measures the functional value of an individual muscle cannot be determined. The writer lacks the mathematical ability to estimate

these factors and questions the practical benefit to be derived, were he able to do so. The present effort is not concerned with determining the actual force exerted by the individual muscles, but with demonstrating first the particular rôle of each muscle and second its relative importance in maintaining foot posture.

Experiment 2. One at a time the individual muscles were freed, tension being maintained upon the others.

With the *tibialis anterior* free the cuboid touched the scale at 13 pounds, the navicular at 48. The force of this muscle is exerted in a direct upward pull on the inner border of the longitudinal arch. Its efficiency is in direct ratio to its pull.

When the *tibialis posterior* was released the outer border of the foot reached the scale under 8 pounds pressure. With increasing weight the medial malleolus shifted backward, the head of the talus downward and the navicular was completely depressed when the scale registered 40 pounds. These combined movements resulted in a caving inward and downward of the mid tarsus. The weakening of the foot resulting from release of the *tibialis posterior* tendon was out of proportion to the 5 pound pull involved. The increase in force of this muscle is accomplished through the action of a virtual lever arm arrangement in the talonavicular articulation. The navicular glides about the head of the talus like a segment on the surface of a sphere. Its center of motion lies in the neck of the talus. The length of its lever arm is the radius of the sphere, that is, the distance from the center of motion to the tubercle of the navicular where the tendon of the *tibialis* is attached. When the navicular becomes the more firmly fixed the head of the talus glides upon it in a reverse direction.

With the *flexor digitorum longus* released the cuboid reached the scale floor at 10 pounds pressure, the navicular at 44 pounds. The malleolus advanced but little more of the movement being accomplished by the talus.

Freeing of the *flexor longus hallucis* let the outer border of the foot down at 13 pounds, the inner border at 40, demonstrating a slightly weaker support of the lateral border

of the foot by this muscle than by the flexor digitorum longus, but a stronger support of the medial border. Weakening of the foot from loss of the flexor hallucis longus was particularly noticeable in the subtalar articulation. The talus and navicular maintained their interrelation more closely than after loss of other muscles but both rotated medially and downward along with the anterior end of the calcaneus to produce the simple eversion type of flat foot without pronounced mid tarsal deformity.

The positions of the tendons of these last two muscles medial to the center of motion in the subtalar talocalcaneal joints give them a moderate mechanical advantage so that their actual pulls are increased somewhat in effect.

Release of the peronei had no effect on the inner border of the foot. The outer border was depressed in each instance under 15 pounds.

This experiment demonstrated two means of support of the longitudinal arch, direct upward pull as exhibited by the tibialis anterior and peroneus brevis in which work accomplished is in direct relation to the force applied, and second, lift from below as shown by the long plantar muscles, which is increased in effect by mechanical advantages of pulleys and levers.

Experiment 3 The leg being held stationary in a vertical position the foot free and all other muscles free 5 pounds pull was applied to each muscle in turn.

The tibialis anterior elevated the inner border of the foot, then dorsiflexed the foot.

The tibialis posterior adducted and plantar flexed the anterior part of the foot on the posterior, then inverted and plantarflexed the foot as a whole.

The flexor digitorum longus, in addition to flexing the four outer toes, inverted and plantarflexed the foot, considerably increasing the arch by plantarflexing the fore part of the foot at the mid tarsal joint.

The flexor hallucis longus inverted the foot less than the flexor digitorum, but plantar flexed it and elevated the arch by the same action at the mid tarsal joint.

The peroneus brevis raised the outer border of the foot then everted and plantarflexed the

TABLE I—RELATIVE EFFICIENCY OF THE DIFFERENT MUSCLES IN MAINTAINING FOOT POSTURE

	Pounds pressure required to depress	
	Talonavicular	Calcaneocuboid
With 5 pounds pull on each muscle	55	7
With tibialis anterior free	48	13
With flexor digitorum longus free	44	10
With flexor hallucis longus free	40	13
With tibialis posterior free	40	8
With peroneus longus free	55	5
With peroneus brevis free	55	15

foot as a whole. The peroneus longus did the same with more efficiency.

This experiment demonstrated the usual textbook actions of these muscles. In a study of the foot's major functions of weight bearing and propulsion they are of minor importance.

DEDUCTIONS FROM STUDY

In studies of flat feet it is recognized that the long plantar muscles play leading rôles in maintaining the longitudinal arch that the tibialis posterior and peroneus longus through their cross insertions are also active in preserving the transverse tarsal arch that the tibialis anterior is primarily a dorsiflexor and that the peroneus brevis functions primarily in stabilizing the leg on the foot laterally.

The tibialis anterior supports the fore part of the longitudinal arch. The importance of this forward support is demonstrated in those instances of metatarsus varus described by Peabody and others, in which there is anomalous insertion of this tendon at the metatarsophalangeal joint. Hallisy in his study of the foot muscles has recorded this as one of the more common variations in insertion of the tibialis anterior. In this condition the anterior tarsus sags laterally while the metatarsophalangeal area is held inward by the anomalous tibialis anterior and the hypertrophied adductor hallucis. Growth of the metatarsals under these abnormal stresses leads to distortion of their shafts. The writer treats this deformity by transplanting the anomalous tibialis to its usual insertion, and

freeing the adductor hallucis from its origin on the calcaneus by Steindler's method. With the faulty stress removed the bones straighten themselves without surgical mutilation.

The tibialis posterior functions in maintaining the malleolotalonavicular relationship in horizontal, vertical and sagittal planes. It is the only muscle acting directly on these parts, and the only one that forces the medial malleolus forward. Its loss allows eversion and depression at the mid-tarsal joint.

The flexor digitorum longus supports the arch by holding the talus upward forward and outward in relation to the metatarsus and the heel. Loss of its support permits depression of the talus and inward rotation of this bone on the calcaneus, the simple type of everted flat foot.

The flexor hallucis longus maintains the arch by elevation and forward lift on the sustentaculum tali of the calcaneus. Its effect is similar to that of the flexor digitorum longus. Though it lacks the latter's lateral insertion it derives from its more medial position a greater power in lifting the inner border of the mid tarsus. Its loss results in the same type of deformity as loss of the flexor digitorum.

The peroneus longus supports the outer border of the foot consolidates the anterior

tarsus and stabilizes the foot and leg laterally. Its loss results in depression of the transverse arch and a tendency for the ankle to turn outward in weight bearing.

CONCLUSIONS

Each of the long plantar muscles plays a specific part in maintaining normal foot posture. Their individual rôles depend more upon their relations to bone and ligament pulleys about the ankle than on their points of origin and insertion. Efforts to preserve or restore the arch must be based more than is ordinarily the custom on the particular need of the individual patient as determined by careful analysis of his disability.

THE BLOOD SEDIMENTATION TEST AND ITS VALUE IN THE DIFFERENTIAL DIAGNOSIS OF ACUTE APPENDICITIS¹

ALBERT LESSER, M.D., AND HAROLD A. GOLDBERGER, M.D., New York

VARIOUS theories for the explanation of the phenomenon of blood sedimentation have been advanced, but the one which is almost universally accepted after considerable experimental investigation is that advanced by Fahraeus, whose work gave renewed interest to a neglected subject. His opinion was that the determining factor in the sedimentation reaction is the seroglobulin and fibrinogen, both of which substances are present in the blood plasma in increasing quantities in the diseased states. This opinion has been recently confirmed by Gilligan and Ernste. Other factors such as the adsorbability of the erythrocytes and carbon dioxide tension of the blood are also mentioned but were shown to be of only secondary importance.

TECHNIQUE

The original Westergren technique was first applied in our study of cases. This procedure was as follows: 4/10 of a cubic centimeter of 3.8 solution of sodium citrate was drawn up into a 2 cubic centimeter syringe, with this same syringe, blood was then taken from a vein to make a total of 2 cubic centimeters. After placing this blood in a test tube and shaking the citrated blood was drawn into a glass tube 2 millimeters in diameter to make a column 200 millimeters in height. This glass tube was placed in a rack and readings of the level of sedimentation of the blood were taken every 10 minutes up to the final hour reading. In doing a large number of cases routinely on admission it was found necessary to modify this technique for purposes of simplicity and speed.

Our modification allowing accurate Westergren interpretation was devised as follows: Test tubes are prepared each containing 30 milligrams of dried sodium citrate; these tubes are kept available in the wards at all times. To perform the test, 4½ cubic centimeters of blood are drawn from a vein, added to a test tube and shaken thoroughly, the test then pro-

ceeds as in the original method. However, readings were taken at the end of 15 minutes and at the end of the hour, the final hour reading being the one referred to in all discussion of the sedimentation rate. In order to simplify the discussion of the various readings of the blood sedimentation reaction in the varied groups of cases, we have divided the gradation of readings as follows:

6 millimeters to 15 millimeters in the hour—normal reaction
15 millimeters to 40 millimeters in the hour—moderate reaction
40 millimeters to 80 millimeters in the hour—high reaction
80 millimeters to 140 millimeters in the hour—severe reaction

CLINICAL CASE GROUPS

In the latter part of 1931, we began to study the blood sedimentation rate in various types of cases in the wards at the Metropolitan Hospital. Our initial interest was to observe the relationship of this sedimentation reaction to the leucocytic response of the blood. These cases finally divided themselves into several large groups on a clinical basis. Two thousand cases both medical and surgical were studied, aligning themselves into the following groups:

1. Pneumonia and complications
2. Tuberculosis
3. Rheumatic fever
4. Pregnancy and complications
5. Acute and chronic salpingitis (adnexal disease)
6. The acute surgical abdomen, with stress on differential diagnosis of conditions in the right lower quadrant

1. *Pneumonia and complications* In general, the study of 60 cases, with an average of 5 weekly readings in each case, revealed a definite index to prognosis in the course of the disease. The acute, full blown case, regardless of type, showed an average reading of 80 to 100 millimeters in the hour and with beginning resolution and convalescence the study of cases showed a gradual decrease in the sedimentation reading. With the onset of

complications, such as pleurisy, empyema, or pericarditis, a sudden sharp increase in sedimentation rate was noted.

2 Tuberculosis. In pulmonary tuberculosis, we have found that the height of the sedimentation reading is an accurate indication of the extent and activity of the pulmonary pathology. Similarly in tuberculous peritonitis, high sedimentation readings were obtained. Fifty cases were studied, our interest being chiefly in allocating various types and degrees of pulmonary pathology in our sedimentation classification. Repeated readings were not done, and indications as to prognosis and treatment were not investigated. Hilary Roche recently contributed an excellent paper on the blood sedimentation with particular reference to its relationship in the course and management of the condition.

3 Rheumatic fever. Forty cases were studied at regular intervals averaging five readings to the case. During the acute clinical phase of the disease the average reading noted was 90 to 100 millimeters in the hour. Here it was found that in taking weekly readings, the sedimentation time gave us a definite prognostic indication as to the course of the disease that is with regression of the disease as noted by improvement of joint symptoms, temperature, etc. there was a definite decrease in the blood sedimentation reaction or with further complications such as increase in joint involvement or cardiac complication, the high sedimentation reading persisted or even increased. Bach and Hill, and Ernestine have made similar observations.

With reference to acute rheumatic fever and its abdominal manifestations, particularly in children it is interesting to dwell on a paper by Plimpton Guptill in which he decries the need for a method or means to be used in the differential diagnosis of abdominal manifestations of acute rheumatic fever from acute appendicitis. The paper quotes a number of cases with an apparent clinical diagnosis of acute appendicitis, which were operated upon, only to reveal normal appendices, and which subsequently developed fulminating multiple joint symptoms. He remarks

'These cases serve to illustrate the difficulties encountered in differentiating appendiceal

inflammation from the pseudo-appendiceal symptoms of rheumatism, especially in view of the fact that Rolly in a series of 3 500 cases of rheumatic fever studied, found evidence of peritoneal inflammation in only 2 cases, and in neither of these 2 cases was there any involvement of the appendix. It is evident in view of the negative findings in the appendix that the clinician must reconsider the means of diagnosis in the hope that some sign will be developed to differentiate these two diseases.

We feel that we can offer a very substantial and satisfactory aid to this problem in the form of the sedimentation reaction. Every case of rheumatic fever in our study even at its earliest incipient stage, showed a sedimentation reading ranging from a high (60 to 80 millimeters in the hour) to a severe (70 to 130 millimeters in the hour) reaction. On the other hand every case of appendicitis studied showed an absolutely normal reading (6 to 15 millimeters in the hour). This rather peculiar phenomenon will be discussed in greater detail further on in the paper. It is interesting to quote an illustrative case.

L. B. colored male, aged 12 years, was admitted to the hospital with a diagnosis of acute appendicitis. The onset of illness was with pain in the epigastrium 4 days previous to admission, followed by anorexia, listlessness, and nausea. This pain shifted just before time of admission to the right lower quadrant. On admission, temperature was 101 degrees, pulse 120, respirations 20. There was marked tenderness over McBurney's point and evidence of peritoneal irritation. Rectal examination was confirmatory, but no masses were palpated. The white blood count was 10 50 polymorphonuclears, 35 per cent band cells, 5 per cent. The sedimentation rate was 104 millimeters in the hour. Because the blood sedimentation reaction was so discordant with that consistently observed by us in acute appendicitis, it was decided to observe the case further. Two days later all abdominal pain disappeared and the patient complained of pain in the right hip in several hours this was followed by the appearance of an acute painful swelling in the right knee.

In this case, we feel that the diagnosis of the abdominal manifestations of acute rheumatic fever was properly differentiated from acute appendicitis with the aid of the sedimentation reaction.

4 Pregnancy and complications. It has been well established since the first observation of

Fahraeus that in pregnancy, beginning with the second month there is a slow graded increase in the sedimentation reading, up to an approximate reading of 45 to 50 millimeters in the hour at term. In incomplete abortions, without sepsis, the blood sedimentation reaction is only slightly higher than that which is normal for the month of pregnancy but with retention of secundines and with onset of sepsis there is a sharp rise in the sedimentation time. In unruptured ectopic gestation, the reading is only slightly higher than that which is normal for the corresponding week of pregnancy. However with rupture and free hemorrhage into the peritoneal cavity the sedimentation reading mounts to 80 to 100 millimeters in the hour varying with the extent of hemorrhage. Friedlander similarly stated "ruptured ectopic pregnancy with fresh blood in the abdominal cavity had a very rapid sedimentation time within the range of acute infections."

5 Acute and chronic salpingitis (adnexal disease) Approximately one thousand cases were studied with a number of readings varying between 1 to 12 per case. This field of work has been thoroughly tilted by many investigators. Polak did a great deal of work along these lines and was firmly convinced of the value and efficiency of this laboratory procedure in gynecology. Baer and Reis using the Lanzemeier technique stated that a negative blood sedimentation reaction at the end of 120 minutes rules out pelvic infection. In our hands the Westergren technique as modified seemed more accurate and more practical indicating more clearly the gradations of pathology and necessitating only the hourly reading. A blood sedimentation reaction less than 20 millimeters in the hour was found to be an absolute assurance of the absence of any acute pelvic infection. On the whole our results confirmed those of previous workers and an optimum time for operation, as determined by the blood sedimentation rate was found. All typical clinical cases of acute adnexal disease were found to have hourly readings varying from a low 40 to 50 millimeters to a high 140 to 150 millimeters depending upon the degree and extent of acute pelvic pathology. Sedimentation

readings were taken at weekly or bi weekly intervals to determine (a) progress of case under treatment, (b) optimum time for operation in those cases in which clinical history and pelvic examination so indicated. It was consistently observed that long after temperature white count, pain and tenderness had subsided the more delicate sedimentation reaction became a much more accurate prognosticator as to the most favorable time for operation. No case was operated upon for adnexal disease until the sedimentation rate was below 25 millimeters in the hour. As a result at no time in several hundred operations were acute processes encountered. This observation was well supported by an excellent record of low postoperative morbidity. A sharp contrast in morbidity and postoperative convalescence was seen in those cases operated upon for adnexal disease (before sedimentation readings became routine) in cases in which only clinical and other laboratory findings were used as indication for operation. Several of these cases ran stormy convalescent courses in spite of apparently favorable operability.

6 The acute surgical abdomen The acute surgical abdominal cases admitted to the emergency wards presented an interesting study in comparing the sedimentation reaction with the leucocytic response. The first surgical emergencies on which the sedimentation test was done were those of acute appendicitis. *Despite a definitely high leucocytic count in these cases in which definite acute appendiceal pathology was demonstrated at the operating table, we were surprised to encounter a normal sedimentation reaction.* Such pathological states as catarrhal, suppurative, or gangrenous appendicitis caused no deviation from the normal sedimentation reaction. The only forms of appendiceal pathology giving abnormal sedimentation reactions were those of well established abscess or generalized peritonitis of appendiceal origin. On the other hand all other conditions producing the clinical picture of the acute surgical abdomen, showed a definitely abnormal sedimentation reaction.

The abdominal conditions other than acute appendicitis in the order of frequency with

which they were found at the Metropolitan Hospital, were as follows

Acute adnexal disease All cases of acute adnexal disease give a sedimentation reaction varying from high to severe (60 to 120 millimeters in the hour) depending upon the extent and virulence of the infection. This fact becomes one of utmost importance, especially so at this institution, where so many cases of acute adnexal disease are admitted with very vague history and clinical findings pointing to the right lower quadrant. The ordinary clinical and laboratory measures, in a good number of cases, have frequently left us undecided as to a definite diagnosis particularly between appendicitis and salpingitis. It soon became evident that the sedimentation reaction offered us a new and distinct aid in the differential diagnosis in this classical dilemma.

between acute salpingitis and acute appendicitis, that is, salpingitis giving a consistently abnormal blood sedimentation reaction and appendicitis a consistently normal one.

The acute surgical gall bladder The acute surgical gall bladder varying from acute suppurative to ruptured gall bladder gives a sedimentation reaction varying from moderate (25 to 40 millimeters in the hour) to high (60 to 80 millimeters in the hour)

Ruptured peptic ulcer Similarly the ruptured peptic ulcer with free fluid in the peritoneal cavity gives an abnormal reaction varying from moderate to severe depending upon the duration of rupture.

Tuberculous peritonitis Tuberculous peritonitis is occasionally met with as a surgical differential from appendicitis and here again this disease falls into the category of those

conditions yielding abnormal sedimentation readings, usually 75 to 90 millimeters in the hour.

Acute conditions of the genito-urinary tract Acute conditions of the genito-urinary tract such as pyelonephrosis, pyelitis, ureteral calculus, and seminal vesiculitis, have on occasion simulated acute appendicitis. In these cases the blood sedimentation reaction has been consistently high.

Masked chest conditions with abdominal manifestations That group of acute chest conditions with referred abdominal manifestations has also entered into a differential diagnosis of the acute surgical abdomen; thus several cases with apparently acute surgical conditions of the abdomen and high sedimentation readings have subsequently proved to have acute pulmonary pathology such as central pneumonia and acute tuberculosis.

Miscellaneous conditions with acute abdominal manifestations Such conditions as ruptured ovarian cyst, ruptured ectopic pregnancy, mesenteric thrombosis, and acute mesenteric adenitis have on occasion entered into the differential diagnosis of the acute surgical abdomen. These conditions have all shown definitely abnormal sedimentation reactions.

TABULATION OF CASES AND COMMENT

We have grouped the cases studied into the following tables: Table I consisting of all cases of acute appendicitis; Table II consisting of a group of other surgical conditions encountered.

Table I demonstrates a clinical, laboratory and operative study of 75 consecutive cases of acute appendicitis falling into the pathological classification of acute catarrhal, gangrenous, and suppurative. It is uniformly observed that the sedimentation reaction regardless of pathology noted has been normal. Age, sex, and casual individual factors do not alter in any appreciable manner the sedimentation reaction in this group of cases. The white counts are found to vary from normal (7,000) to 30,000 and the percentage of polymorphonuclears varies from 65 to 95 per cent without any bearing or relationship to the consistently normal blood sedimentation

reaction. In those cases in which Schilling or Armeth indices were done, no relationship to the sedimentation reading was noted.

Table II enumerates that group of cases other than acute appendicitis as proved at operation or by subsequent clinical course of the condition. A study of this group of cases illustrates the variety of conditions encountered in the surgical differential diagnosis of the acute appendix. The sedimentation readings were uniformly abnormal, regardless of the diagnosis. No consistent relationship between the white cell count and blood sedimentation reaction was noted although in some cases, e.g., in extensive suppuration high sedimentation readings were accompanied by high white cell counts. It is important to note that cases of appendiceal abscess are grouped under Table II inasmuch as such cases present a definite distinction, both on a clinical and pathological basis, from acute appendicitis *per se*. These cases have shown distinctly abnormal readings, varying from 40 to 100 millimeters in the hour; likewise, frank cases of generalized peritonitis though appendiceal in origin are grouped in the above table.

To demonstrate the value of the sedimentation reaction as an aid to differential diagnosis, we wish to quote several of the numerous cases encountered in which the sedimentation reaction proved to be a distinct guide to diagnosis.

CASE 1. D. L., a colored female child, 10 years of age, was admitted to the hospital with a diagnosis of acute appendicitis. Thirty-six hours before admission she was seized with severe pain in the epigastrium soon followed by nausea and vomiting. On admission the pain was described as having migrated to the umbilicus and lower right quadrant. Past history was essentially negative. On examination there was found marked tenderness in the right lower quadrant and slight spasm. The temperature was 99, pulse 100, respirations 22. The white blood count was 10,700—polymorphonuclears 71 per cent; the blood sedimentation rate was 40 millimeters in the hour. Because of aggravation of symptoms, laparotomy was done, revealing an acute salpingitis with normal appendix.

CASE 2. A. F., adult colored male, aged 24 years, was admitted to the hospital with diagnosis of acute appendicitis. There was a history of pain in right lower quadrant for past 2 days with nausea but no vomiting. He had taken an enema and cathartic

with aggravation of symptoms. On examination the patient was found to be acutely ill, temperature was 100, pulse 100, respirations 22. There was spasm and tenderness with hyperaesthesia of the right lower quadrant. On rectal examination, an acutely tender boggy seminal vesicle was palpated on left side. On further questioning the history was obtained of gonococcal arthritis 4 years previously with recurrence of slight urethral discharge 1 month ago. The white blood count was 10,400, 75 per cent polymorphonuclears, blood sedimentation rate 65 millimeters in the hour. The urine showed moderate pus cells and shreds. The patient was transferred to genito-urinary service where he underwent treatment for seminal vesiculitis with relief of condition.

CASE 3. J. B. Porto Rican male, aged 26 years, was admitted with diagnosis of acute appendicitis. Three days before admission patient began to suffer severe right lower quadrant pain followed by nausea and vomiting. On examination, patient appeared acutely ill, temperature was 101, pulse 120, respirations 22. There was marked muscle spasm and tenderness in right lower quadrant. The white blood count was 7,600, polymorphonuclears 67 per cent, blood sedimentation rate 70 millimeters in the hour. Further examination, with X ray and fluoroscopy revealed an acute caseous pneumonic tuberculous of the right apex, despite the fact that there were no symptoms referable to the chest. Shortly thereafter the abdominal symptoms subsided entirely and the patient is now receiving pneumothorax treatment.

CASE 4. W. C. 33 year old married Porto Rican female, was admitted with diagnosis of acute appendicitis. There was a history of recurrent attacks of pain in right lower quadrant, the last attack being of 24 hours' duration. The temperature was 102 degrees, pulse 110, respirations 24. There was tenderness, spasm, and rigidity over right lower quadrant extending posteriorly to the flank. The white blood count was 13,400—88 per cent polymorphonuclears, sedimentation time 114 millimeters in the hour. The urine showed albumin 3 plus, occasional red cells and moderate pus cells. Cystoscopy and pyelography revealed a pyohydronephrosis with stone in pelvis.

CASE 5. A. W. white female, aged 17 years, was admitted to hospital with diagnosis of acute appendicitis. There was a history of an attack of pain in right iliac region radiating to right lower quadrant 1 day previous to admission, there was nausea but no vomiting. The patient had had similar spasmodic attacks of pain during the past 2 years. On examination, patient appeared acutely ill, temperature was 103 degrees, pulse 114, respirations 24. The abdomen revealed tenderness and spasm below and to the right of the umbilicus. The white blood count was 10,200—76 per cent polymorphonuclears, blood sedimentation rate 70 millimeters in the hour. Appendectomy was performed and appendix was found to be entirely normal. After operation, the patient developed signs of increasing fluid in the right

chest, these findings were confirmed by X ray, chest was tapped and patient placed under medical treatment.

SURVEY OF THE LITERATURE

On completion of the work outlined, it was interesting to survey the contemporary literature on the subject. The references were comparatively meagre and on the whole discordant. M. Cattaneo in 1932 studied 40 cases of acute and chronic appendicitis. His conclusions are completely contradicted by our results. He states "In subacute and chronic appendicitis, the sedimentation velocity of erythrocytes increases with the increase in leucocytes. In acute appendicitis, the sedimentation velocity increases also in those cases in which no increase in leucocytes appears—but as it seems more constant in acute cases and is earlier as compared to the leucocytosis, it may furnish useful indications in appendicitis—as to the existence of the inflammatory condition." It will be readily seen that the conclusions drawn by this writer in a short series including chronic cases is contradicted in every respect by our results. M. Montanari Reggiani studied the "Numerical variations of the leucocytes and the conduct of the sedimentation rate in cholecystitis, appendicitis and adnexitis." We agree with his general observation that there exists in none of these infections a specific conduct or a correspondence between a degree of leucocytosis and the time of sedimentation but we thoroughly disagree with his impression that no differential diagnostic data between these three diseases can be obtained. The essential purpose of our study after a two thousand case series is to clearly demonstrate the striking value of the blood sedimentation reaction in the differential diagnosis of appendicitis.

E. G. Bannick presents an excellent paper on the sedimentation reaction covering a wide variety of conditions. His generalizations are concise, and our studies concur in every respect with his results. We have independently concluded as he does that "the chief information concerning the rapidity of the sedimentation of the blood is provided during the first hour—and the simplest way of expressing this is by measuring in millimeters

TABLE III.—AGE AND SEX IN SKIN MALIGNANCIES

	Age																	Sex	
	6	9	16	19	30	1	2	3	24	25	26	27	28	29	30	31	32	M	F
Basal cell epithelioma							2			4			2			2		6	4
Squamous cell epithelioma	1		1			1			1	1		1						6	3
Nævus cell carcinoma		1	1		1				2			1	2					8	1

Twenty seven patients suffering from malignant disease of the skin were 30 years of age or younger. Of these 10 had basal cell epitheliomata, 8 squamous cell epitheliomata, and 9 nævus cell carcinomata.

The 10 basal cell lesions all began as small sores or pimples which did not heal. Two of the patients gave a history of a burn as the beginning of their present illness and one, the history of cutting himself several times with a razor. The duration of these symptoms varied from 6 months to 10 years.

All but one of the lesions were treated successfully. That is, all healed following original treatment. One was lost trace of 1 month later, the remainder have been well for periods varying from 1 year to 18 years with the exception of the patient who had two lesions, one on the left lower eyelid and one on the right lower eyelid.

This patient had both lesions at the time of admission. Both healed with radiation treatment but the right one recurred after 3 years. The lesion was re-treated but the patient neglected the condition and did not report for re-examination until the lesion was far advanced. Irradiation was again tried but was unsuccessful. Eventually the entire orbital contents and eyelids were coagulated, but the disease spread gradually causing death 19 years after admission. The lesion on the other eyelid remained healed at the time of death.

Treatment of the squamous cell lesions also met with considerable success. Five of the 8 patients have remained clinically well following original treatment for periods varying from 1 year to 6 years, 1 patient was unimproved and lost in 1 month, 2 were progressively worse and died from the disease. Both of these latter patients gave a history of having been treated with X ray for lupus for several years before admission. Two other patients gave a history of having been burned at the site of the lesion one of being cut with

a razor at the site of a wart, and another lesion occurred at the site of a birthmark.

These skin malignancies were treated by means of unfiltered X rays, two to five times the erythema dose, in one sitting, radium plaques, or filtered radium. The regional lymph nodes in the squamous cell cases were treated by means of 200 kilovolt X rays or large radium packs. In some cases surgery or coagulation was resorted to according to indications.

There were 9 cases of nævus cell carcinoma. Three of these patients gave a history of a growth of a mole which had existed since birth. Only 1 patient gave a history of injury at the site of the lesion. All the lesions were removed surgically and treated with 200 kilovolt X rays or radium packs. The result of this treatment is as follows.

One patient is alive and well 9 years 5 months after treatment, 1 patient was clinically well for 2 years 5 months when there was a recurrence and he died 5 years 9 months after admission from general carcinomatosis, 1 patient was well for 8 months and then there was a recurrence. He eventually died from the disease 3 years 7 months after admission. Four patients died within a year with no improvement, 2 were lost trace of in 6 months and 8 months respectively. Both were unimproved.

It is a fact that most basal cell and squamous cell epitheliomata, and also nævus cell carcinomata, occur later in life the majority occurring after the age of 40.

ORBITAL CAVITY

There were 20 cases of malignancy involving the orbital cavity in patients under 30 years of age. Twelve were retinoblastomata (glomata) 2 squamous cell epitheliomata of the conjunctiva, 1 basal cell epithelioma of

TABLE IV—AGE AND SEX IN ORBITAL CAVITY TUMORS

	Age												Sex	
	1	2	3	4	5	6	7	8	9	10	11	12	M	F
Retinoblastoma (gloma)		1	1										2	1
Epithelioma conjunctiva														
Basal cell epithelioma cornea													1	
Carcinoma lacrimal gland										1				1
Sarcoma						1								

the cornea 2 carcinomata of the lacrimal gland and 3 sarcomata. Table IV shows the age and sex of these patients.

Retinoblastoma is a disease which usually occurs in children. Most of the cases occur before the age of 5 years. Usually parents or guardians discover some abnormality in sight from the actions of the children and finally notice a dilated pupil with a grayish color. These symptoms were noted as early as 6 weeks after birth in our group of cases. In 1 of our cases 83 per cent the disease was bilateral. Stout quotes Morax as saying that 28 per cent of these tumors are bilateral.

If seen fairly early there is a fair prospect of surgical cure. When the disease has permeated the globe (the glaucomatous stage) or penetrated the globe, the prognosis is grave. Stepka, as quoted by Stout, says that in all cases where it had perforated the globe the results were bad. Ten of our cases had had enucleation of the affected eye. All were treated by radiation, either 100 kilovolt X-rays, or radium applications. Eight died in less than a year 1 was lost trace of in 3 months, the result undetermined, 1 was lost trace of 2 years after admission, at which time there was no recurrence 1 was clinically well for 9 months and then lost trace of and one has been clinically well for 3 years and 4 months following surgical removal and 11 radiation.

Both cases of squamous cell epithelioma of the conjunctiva were biopsied and treated with a large amount of radon lightly filtered and have remained clinically well since the time of original treatment. The one, a 19 year old male, for 10 years the other an 18 year old female, for 2 years.

The basal cell epithelioma of the cornea occurred in a 16 year old male. This lesion was biopsied and treated with a large amount of radon lightly filtered and has remained clinically well for 1 year and 7 months since treatment.

The 2 carcinomata of the lacrimal gland were tumors of the mixed salivary type. Both were treated by radiation followed by surgical removal of the tumor. One patient died in 2 years from metastases throughout the skull and scalp and the other patient lived over 6 years and was free from recurrence at last observation. Both were females, aged 27 and 28 years respectively.

The 3 other cases of malignancy involving the orbit were sarcomata.

One was a round cell sarcoma in a 15 month old female. The eyeball was enucleated and the tumor removed but the baby died the following day. Autopsy revealed metastases to the lungs, kidneys, and bladder.

The second case was in a 14 year old male and biopsy showed a mixed cell sarcoma containing spindle round, and myxosarcoma. The tumor was dissected from the orbit and radium needles were inserted following which he was clinically well for 7 months. The lesion then recurred and was again treated with the insertion of radium needles and the application of the 4 gram radium pack. He has been clinically well for the past year.

The third, in a 30 year old female, was a melanoma which was treated with 100 kilovolt X-rays followed by enucleation of the eye. This patient died 4 years 6 months after admission, from recurrence of the lesion in the orbit and spinal metastases.

BRAIN

There were two brain tumors. One was a cerebellar tumor in a 6 year old male on whom a decompression had been done before admission. This child complained of headaches, and

had been troubled by nausea and vomiting for 3 months. He was treated with 200 kilovolt X rays and he died 3 months after admission. The second case was a medulloblastoma of the floor of the fourth ventricle in a 12 year old female. Tissue had been removed at the time of admission and 200 kilovolt X-rays were given. This child had palliation for 7 months when there was a return of her symptoms and progression of the disease and she died 1 year after admission.

LIP

There were 4 cases of epithelioma of the lip (10), in patients aged 25 27 28 and 29 years, respectively. All were males. In 3 the lesion was confined to the lip and there were no palpable nodes in the neck in the fourth there were small nodes in both the right and left submaxillary regions. All of these patients used tobacco and all had poor oral hygiene, 2 had positive Wassermann reactions. The sections in all the cases were found to be squamous cell epitheliomata. All have remained well since treatment except that 1 still has a small palpable node in the submaxillary region, 1 remained well for 2 months and was then lost trace of 1 for 6 years, 1 for 8 months, and 1 for 7 months (this is the one with the node). These cases were treated with unfiltered X rays to the lip and 200 kilovolt X rays to the lymph bearing areas. These patients gave histories of a cold sore scabbed lesion, or small ulcerations which had existed for from 3 months to 1 year.

ORAL CAVITY

There were 23 cases of malignancy involving the oral cavity in which the patients were under the age of 30 years. One was a papilloma-like growth inside the upper lip in a 23 year old female which showed beginning epithelioma and was treated by the implantation of radon seeds. The tumor regressed following treatment but the patient was lost from observation.

There were 11 cases of malignancy of the gum 3 were epitheliomata in 18 22 and 26 year old males, all used tobacco oral hygiene was fair; one had a positive Wassermann reaction. Biopsy in the 3 cases showed epithelioma.

The histories given were of a growth or sore which had been noticed for from 2 months to 2 years. All of these lesions involved a large area. Two of the patients were treated with radium applied to the lesion and 1 of these also had excision of the whole lesion the third was treated with 200 kilovolt X rays only. All died within a year.

There were 5 cases of adamantinoma of the jaw in patients aged 4, 12 14, 25 and 28 years 2 were females and 3 were males the Wassermann was positive in 1 case all the lesions occurred at the site of canines teeth or some abnormal dental condition.

The lesion in the 12 year old female was not treated, the rest had removal of the tumor mass followed by radium applications.

The 4 year old male was lost trace of in 1 year 11 months the lesion had progressed.

The 14 year old male died 10 years 9 months after admission. The tumor had grown very large, ulcerated, perforated the cheek, and caused a large swelling a the side of the head, but he had had palliation for a number of years. Resection of the jaw had been refused in this case.

The 5 year old male was clinically well for 1 month when he was lost from observation.

The 25 year old female, a colored woman, was clinically well for 3 years. Since then the lesion has recurred on 3 occasions. Curettage and irradiation have been palliative over a period of 10 years.

One case, a 11 months old male, had an injury to the jaw followed by tumor formation. Section of this showed round cell sarcoma. He was treated with 200 kilovolt X-rays followed by complete disappearance of the tumor. The baby died 3 1/2 months later from other causes. A fibromyxosarcoma of the gum occurred in a 5 year old male and involved the jaw bone. This was removed surgically and then treated with 200 kilovolt X-rays and there has been no recurrence for 7 years 9 months.

An alveolar sarcoma occurred in a 19 year old female. This was treated with a large amount of radon lightly filtered, and the implantation of radon seeds. This patient has been clinically well for the past 7 years.

Four of these malignancies of the oral cavity occurred on the palate.

One was an epithelioma in the soft palate area with a palpable node in the right submaxillary region in a 13 year old male. The lesion was treated by the implantation of gold radon seeds and the nodes in the submaxillary region were treated with 200 kilovolt X-rays. This patient has been clinically well for 3 years.

TABLE V—AGE AND SEX—ORAL CAVITY AND LIP MALIGNANCIES

	Age																				Sex	
	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	M	F			
Epithelioma																						
Adenoma fibroma																						
Sarcoma																						

Two were myxosarcomata.

One occurred in a 29 year old male and involved the hard and soft palate regions. He was treated with radium packs but died 11 days after admission from acute dilatation of the heart. Autopsy revealed that this lesion had invaded the bone.

The other myxosarcoma occurred in a 10 year old female and involved the soft palate with a peritonsillar node on the right side. This patient remained clinically well 2 years 11 months following treatment with 200 kilovolt X rays but the lesion then recurred, causing her death 3 years 4 months after admission.

The fourth case was a fibrosarcoma in the hard palate in a 25 year old male which was treated with radon seeds. He has remained clinically well for 3 years.

Three of the cases involved the tongue all lesions were squamous cell epitheliomata showing pearls and occurred in 24 and 30 year old males and a 30 year old female. None of these patients used tobacco. In 1 case the teeth were in very bad condition and a second patient had been undergoing treatment for syphilis all the Wassermann reactions were negative at the time of admission. The symptoms given were those of a "sore" on the tongue which had been present for 2 or 3 months in each case.

The growth in the 24 year old male was very far advanced with a large tumor mass in the submandibular region which was fixed to the jaw bone. X ray treatments with 200 kilovolt X rays were given but the patient died without palliation in 5 months.

The lesion in the 30 year old male involved the left side of the tongue at the junction of the middle and posterior thirds and looked like an old leucic lesion undergoing malignant change. This was treated with radon seeds into the tongue and 200 kilovolt X-rays to the neck. The patient was clinically well for 10 months when he committed suicide.

The lesion in the 30 year old female involved the left side of the tongue near the base. It was treated by the implantation of radon seeds and 200 kilovolt X rays. The patient died in 3 months without improvement.

One case, an epithelioma of the tonsil and base of the tongue, was treated by the implantation of radon seeds and the radium pack. Within 1 month radical surgery was done at another hospital. The patient died 8 months after admission from the disease.

Three cases occurred in the pharynx, 1 was a transitional cell epithelioma in a 14 year old male and involved the posterior pharyngeal wall. It was a hard fixed lesion 4 centimeters in diameter with palpable nodes in both sides of the neck.

This patient was treated with the 4 gram radium pack and has remained clinically well for 2 years.

The second case was a lymphosarcoma in the pharynx with a hard metastatic node in the peritonsillar region. It was treated by means of radon seeds implanted into the tumor and 200 kilovolt X rays to the neck. The patient died in 4 months.

The third case was a spindle cell sarcoma of low grade malignancy in a 27 year old colored male, which involved the pharynx, arising from the left side of the base of the tongue. This entire tumor mass was removed surgically but the patient was lost trace of 2 months later.

NASAL CAVITY

There were 15 cases of malignancy which occurred in the nasopharynx: 5 epitheliomata, 4 lympho-epitheliomata, and 6 sarcomata. Table VI shows the ages and sex of these patients.

The symptoms in the cases of epithelioma, lympho-epithelioma, and lymphosarcoma had existed in most instances for from 2 to 6 months in only 2 cases for more than 6 months. These symptoms were headaches, sore throats, or earaches, followed by shortness of breath, obstruction to breathing in one or both nostrils and in most cases, swelling of the nodes in the neck, either one or both sides. Two patients had bleeding from the nose and 2 mucous discharge from the nose. Several complained of difficulty in swal-

TABLE VI.—AGE AND SEX—NASAL CAVITY MALIGNANCIES

	Age																Sex	
	9	14	17	18	20	21	22	23	24	25	26	27	28	29	30	M	F	
Epithelioma				1		1					1				1	1	1

Lymphosarcoma							1		1							1		
Alveolar sarcoma				1												1		
Myxosarcoma	1	1														1		

lowing and 2 coughed up phlegm and blood. The 2 patients with myxosarcoma gave histories of longer duration, one 3 years and the other 9 years. This latter child was thought to have adenoids breathing gradually became completely obstructed and at the time of admission the growth filled both nostrils and the pharynx.

The 5 cases of epithelioma had biopsies.

The 18 year old female was treated with 300 kilovolt λ rays. She died in 2 days from an embolism and autopsy showed metastases in the liver.

The 20 year old male was treated by the implantation of radon seeds and further treatment had been planned, he did not return, however, after this preliminary treatment and died 5 months after admission.

The 3 other cases were treated by radon seed implantation into the nasopharynx and external irradiation—300 kilovolt λ rays or radium packs—to both sides of the neck. In one case the lesion in the nasopharynx completely disappeared but 8 months after treatment a metastasis developed in the groin and the patient died 13 months after admission from metastases in the liver pelvis, and retroperitoneal nodes, the lesion in the nasopharynx remained well at the time of death.

The 2 other patients died in 6 months and 3 years 2 months, respectively from progression of the disease.

There were 4 cases of lympho-epithelioma occurring in 14 and 24 year old females and 17 to 21 year old males. All were treated externally, one by 200 kilovolt λ rays and the other 3 with the 4 gram radium pack. Those treated with the radium pack had supplementary treatment by means of radium tubes inserted through the nares. One patient died in 1 month, 1 has been clinically well for 1 year 3 months, and the other has had palliation for 1 year 5 months. The patient who was treated with λ rays only, died in 6 months.

The 3 cases of lymphosarcoma of the nasopharynx occurred in 22, 24 and 26 year old males.

In the 22 year old male the disease was far advanced. Treatment consisted of surgical removal of the tumor from the orbit and nose and the patient died 10 months after admission from extension of the disease.

The 24 year old male was treated with 200 kilovolt λ rays and the insertion of a radium tube through the nares but he died from sarcomatosis in 9 months.

The third case, the 26 year old patient, was treated with the 4 gram radium pack, following which there was complete disappearance of the lesion. Seven months later there was a recurrence which was treated with radium tubes inserted through the nares and 200 kilovolt λ rays to the right neck. Now 3 months later there is no evidence of the disease.

The alveolar sarcoma in the 18 year old male was treated with the radium pack but the man died 7 months after admission from local progression of the disease and sarcomatosis. The 9 year old male with a myxosarcoma was a very far advanced and hopeless case and was not treated. The 14 year old male with a myxosarcoma was treated by means of radon seeds and tubes and has been clinically well for 13 years.

It is remarkable to note that 53 per cent of the cases which involved the nasopharynx occurred in Italians.

SALIVARY GLAND

Of the tumors involving the salivary glands, totalling 16, 2 were outspoken malignancies, 1 was a spindle cell sarcoma and 1 a lymphosarcoma of the parotid gland. Fourteen of these tumors were of the mixed salivary type involving the parotid gland in 7 cases, submaxillary in 3 cases, inner cheek in 2 cases, inner upper lip in 1 case and the hard palate in 1 case. We have included the so called mixed salivary tumors because it has been our experience that these tumors do show

TABLE VII.—AGE AND SEX IN SALIVARY GLAND MALIGNANCIES

Mixed salivary tumor																	6	1
Spindle cell sarcoma																		
Lymphosarcoma																		

malignant tendencies in that they recur extend, and even metastasize, causing death. This is shown in one of the cases reported here the tumor occurred in a 26 year old male recurred twice, and now shows metastases to the mediastinum and bones (fifth lumbar vertebra and tibia).

The symptoms in the cases of mixed tumor were gradual, painless swellings which had existed for from 3 weeks to 5 years before admission. Three patients noticed this swelling less than 6 months before seeking advice 4 between 1 and 2 years, 3 between 2 and 3 years, 1 for 3 years 1 for 4 years, and 2 for 5 years.

Eight of the 14 patients with mixed tumors had had surgical removal of the tumor before admission. One patient who had had no recurrence was not treated. Eight months after admission there was still no recurrence. In 4 of the patients there was a thickened scar at the time of admission 3 of them were treated with 200 kilovolt X rays and 1 with the 4 gram radium pack. These 4 have been clinically well without recurrence 1 for 5 years, 1 for 5 years 4 months, 1 for 4 years when she was lost trace of and 1 for 11 months since the time of admission. In 3 patients the disease had recurred following surgery. These also were treated with 200 kilovolt X rays. One was lost trace of in 1 month. In 1 the tumor remained stationary for 8 years when it was again removed surgically and the patient has been free from the disease for the past 5 years. In the third case, the tumor was held in check for 2 years 7 months when it began to grow. In spite of irradiation it has continued to grow and has metastasized to the mediastinum and bones (fifth lumbar vertebra and tibia).

One patient who had had biopsy before admission was treated with 200 kilovolt X

rays and died in 2 months. The disease was far advanced.

The 5 other cases of mixed tumor were treated in the following manner.

An 11 year old female had biopsy followed by 200 kilovolt X ray treatment and the tumor has remained stationary for 4 years 3 months.

An 18 year old female was treated by radon seeds implanted into the lesion. This was improving when she died 2 months after admission from a chorionic epithelioma.

A 20 year old female treated with 200 kilovolt X rays and removal of the tumor and radium inserted into the wound, has been clinically well for 9 years.

A 26 year old female had biopsy and the tumor was treated with radium pack and only a thick scar has been present for 5 years.

The 30 year old male was treated with 200 kilovolt X rays and radon seeds. This lesion was on the hard palate and was very far advanced at the time of admission and the man died 3 months later.

The patient with the spindle cell sarcoma in the parotid gland gave a history of being struck by a stone 4½ years before admission, following which he noticed a swelling in the parotid region. The growth was removed surgically treatment with 200 kilovolt X rays followed, and finally the lesion was coagulated. The tumor recurred after coagulation and caused death 6 months later.

The lymphosarcoma of the parotid in the 30 year old female had been removed 10 years before admission, recurred 2 years after removal, and grew gradually. This woman was treated with 200 kilovolt X rays and 4 years 8 months after admission died of a hemorrhage from the ulcerating lesion.

THYROID

There were 3 cases of malignancy of the thyroid (11) all the patients were females, aged 14, 24, and 30. Two of the tumors were carcinomata and 1 was an adenocarcinoma.

The 14 and 24 year old patients noticed a lump in the neck which grew gradually and caused coughing and choking spells. One had existed for 3 months and one for 4 months at the time of admission.

The 30 year old patient had had a goiter for 15 years which gradually became larger and for a few

TABLE VIII.—AGE AND SEX IN RESPIRATORY TRACT MALIGNANCIES

	Age												Sex	
	13	20	21	22	23	24	25	26	27	28	29	30	M	F

months before admission she had had difficulty in swallowing and some pain.

Two had had thyroidectomy followed by irradiation and are alive and well for 1 year 6 months and 2 years 5 months, respectively.

The 14 year old patient had biopsy and treatment with the 4 gram radium pack but died in 3 months.

BRANCHIOGENIC TUMORS

There was 1 case of branchiogenic epithelioma in a 29 year old male who had noticed swelling of the nodes in the left side of his neck for 7 months. Biopsy was taken and he was treated with 200 kilovolt X rays on 2 occasions and he died 1 year 3 months after admission.

RESPIRATORY TRACT

The malignancies of the respiratory tract include 1 epithelioma of the epiglottis, 3 epitheliomata of the larynx, 2 carcinomata of the bronchus, 1 lung carcinoma, 1 endothelioma, 1 carcinoma and 4 tumors (not proved histologically) of the mediastinum, and 2 endotheliomata of the pleura. The ages and sex are shown in Table VIII.

The patient with the epithelioma of the epiglottis complained of a sore throat for 2 months. Biopsy revealed an epithelioma. The lesion was implanted with radon seeds but the patient did not return after treatment, so the result is undetermined.

Portmann and Phillip in an article on cancer of the larynx in the young, review the literature and find only a score of cases. They say it is rare before the age of 30. Only 3 of 160, or 1.8 per cent of our cases, occurred in patients 30 years of age or younger.

In the case of epithelioma intrinsic larynx in the 20 year old female, the patient complained of hoarseness for 2 years before admission. Treatment was

incomplete and the patient was lost from observation.

The 25 year old male was a switchman in a rail road yard. He gave a history of a chronic laryngitis of long standing due to irritation from soot. This patient was treated by laryngectomy followed by 200 kilovolt X rays. He has been clinically well for the past 6 years.

The 30 year old male complained of hoarseness for 15 months before admission followed by choking sensations. He was treated by tracheotomy and low power filtered X ray and died in 6 months.

The 2 carcinomata of the bronchus occurred in 29 and 26 year old males. One was not treated, the other died 3 days after admission and autopsy showed carcinoma of the bronchus with metastases to the liver and both adrenals.

The 24 year old male with carcinoma of the lung was treated with the 4 gram radium pack but died 2 months after admission. Autopsy showed a large tumor in the lung and in the mediastinal and bronchial nodes, and metastases in the cervical lymph nodes. This patient had what he thought was a cold, with shortness of breath, a feeling of pressure in his chest, and difficulty in swallowing for 3 weeks before admission.

The 26 year old male with endothelioma of the pleura was admitted complaining of swelling of the nodes in the groin which were removed. The area was then irradiated. This man succumbed in 9 months from generalized metastases and autopsy showed a primary endothelioma of the pleura.

The 21 year old female with endothelioma of the pleura was treated with 200 kilovolt X rays and died in 5½ months. Autopsy showed a primary tumor of the parietal pleura on the right side with multiple extensions to mediastinal, abdominal and retroperitoneal lymph nodes to both kidneys, mesentery of intestines, and diaphragm.

The 22 year old male with endothelioma of the mediastinum had a biopsy of one of the cervical nodes. He was treated with radium packs but was lost trace of in 1 month.

TABLE IX.—AGE AND SEX IN GASTRO-INTESTINAL TRACT MALIGNANCIES

	Age												Sex	
	9	20		22	3	24	5	26	7	28	29	30	M	F
Stomach														
Sigmoid														
Rectum and anal canal							3				3	6		9

The carcinoma of the mediastinum occurred in a 21 year old male.

This patient died the day following admission and autopsy showed a tumor of the mediastinum, weighing 1,000 grams, the histology of which was carcinoma. The primary site was thought to be aberrant thyroid.

The 4 mediastinal tumors, not proved histologically occurred in patients 13, 22, 28 and 29 years of age respectively. Three were males, 1 female.

The 13 year old male and the 28 year old female were not treated.

The 22 year old male had radium pack treatment but he died in 1 month with no improvement.

The 29 year old male was treated with 200 kilovolt X rays following which his symptoms improved. The tumor remained stationary 4 years 3 months after admission.

GASTRO-INTESTINAL TRACT

There were 24 cases of malignancy of the gastro-intestinal tract: 2 carcinomata of the stomach, 3 adenocarcinomata of the sigmoid, 18 carcinomata of the rectum and 1 epithelioma of the anal canal. Table IX shows the ages and sex.

Both cases of carcinoma of the stomach were inoperable were treated with 200 kilovolt X rays and died in 4 months and 5 months respectively. Both of these patients complained of gastric distress which was chiefly the uncomfortable feeling of gas, 1 for 4 months and 1 for 1 year before admission. Ewing says of carcinoma of the stomach: "While the disease is distinctly one of advanced age, its rather frequent occurrence between 20 and 40 years, and even between 30 and 35 is noteworthy. Fowler reported 9 cases of carcinoma of the stomach before the age of 26 years."

Two of the patients suffering from adeno-

carcinoma of the sigmoid were operated upon and then irradiated; the other was irradiated only. This latter patient died 2 weeks after admission and autopsy confirmed the diagnosis. The 29 year old female who had a positive Wassermann reaction died in 8 months but the 21 year old male is living and well for almost 2 years since admission.

Fowler (2) in reviewing carcinoma of the large bowel and rectum occurring in patients below the age of 26 calls attention to the seriousness of these lesions. No rectal case in his series survived one year. Crippa, quoted by Ewing, found only 3 cases of carcinoma of the rectum between 20 and 30 years in a review of 380 rectal cancers. In our series there were 18 out of 634 cases.

Biopsies from 15 cases of carcinoma of the rectum showed gelatinous carcinoma in 3 cases, adenocarcinoma in 10 and carcinoma in 2. Three very far advanced cases had no biopsy. Biopsy from the lesion in the anal canal showed squamous cell epithelioma with pearl formation.

Three of these patients had been operated upon for hemorrhoids before admission but the primary lesion was not discovered; 2 had had colostomies performed. The chief complaints were pain, bloody and mucous discharge, constipation and diarrhoea. The duration of these symptoms varied from 2 months to 2 years; most patients had symptoms for less than 8 months.

All the rectal lesions were far advanced at the time of admission. Three were not treated. The others were treated by radiation, usually radon seeds implanted into the growth and supplemented externally with either radium packs or 200 kilovolt X rays. In a few cases external irradiation only was given. Eight patients died in less than 6 months, 2 in from 6 months to a year, 4 in from 1 to 1½ years.

TABLE V.—CARCINOMA BREAST
Primary Group I Cases (6 cases)

Age	Marital status	Lactation	Duration before admission	Treatment	Section	Result
1	S		1 mo.	Amputation and irradiation	Carcinoma	Died 6 months
15	S		3 yrs	Amputation and irradiation	Carcinoma	Clinically well 1 yr. mo.

27	S		1 yr 6 mo.	Amputation and irradiation	Carcinoma	Clinically well 4 yrs. Recurrence with widespread metastases. Lost 3 yrs 4 mo. after admission
28	M	2 normal pregnancies	1 yr	Amputation and irradiation	Carcinoma	Died 1 year

†1 year

Primary Group III Cases (4 cases)

29	M	3 normal pregnancies (time of last pregnancy 3 yrs. ago breast painful and swollen)	1 yr 9 mo.	Irradiation only	Adeno-carcinoma	Lost trace of 1 yr 3 mo.
30†	M	3 normal pregnancies	3 weeks	Not treated	None	Not treated
30	M	4 miscarriages	8 months	Irradiation only	None	Died 3 months
30	M	2 normal pregnancies	7 months	Amputation and irradiation	Carcinoma	Died 1 yr 3 mo.

†5½ years 12 years ago

and 1 patient is living 3 years 6 months after admission and is having palliation

The epithelioma of the anal canal occurred in a 24 year old female and was far advanced when the patient was admitted. This was treated with 200 kilovolt X rays and the woman died 1 year 5 months after admission.

The 1 case of carcinoma of the mesenteric nodes occurred in a male, aged 28 years. The primary site was not found in this case and the patient died in 2 weeks. The lesion was revealed by exploratory laparotomy.

BREAST

Twenty five patients with breast carcinoma were 30 years of age or younger. This is 13 per cent of the total number of breast car-

cinomata admitted to this institute. Of these 25 14 were primary tumors and 11 were recurrences after operation.

Ewing says, "Before 30 years of age mammary cancer is extremely fatal so that some surgeons prefer not to operate during this period. Schwartzoff reports 15 such cases, all rapidly fatal in spite of early operation." Lee is strongly of the opinion that cancer of the breast in young women is a much more menacing disease than it is in middle life or old age. Of 51 of his cases in patients under the age of 30 years 30 were treated by radical operation and only 17 per cent survived 3 years. Stout also is of the opinion that "cancer free survivals are decidedly fewer below the age of 35." Matthews, on the other hand,

TABLE XI—CARCINOMA BREAST
Postoperative Recurrent Cases (11 cases)

Age	Marital status	Lactation	Duration before admission	Length of time since operation	Duration of recurrence	Section	Result
26	S		4 yrs 6 mo	4 yrs.	2 yrs.		Died 6 yrs 9 mo from admission (good palliation from irradiation)
26	M.	normal pregnancy	1 yr	4 mo	1 mo.	Carcinoma	Died 7 yr. 3 mo

30	M	4 normal pregnancies	1 mo				Not treated
30	M	3 normal pregnancies	17	1 mo			Died 4 mo
30	M		17 4 mo	17 6 mo	1 mo		Died 17 mo

NOTE.—All deaths were due to widespread metastases in lung.

in reviewing the 10 year survivals of mastectomy says. The younger patients, contrary to common belief do quite as well following operation as the average patients.

According to Deaver and McFarland 13 per cent of all tumors of the breast before the age of 30 are cancer. They quote Rodman as saying that 9 per cent of all tumors of the breast before the age of 30 are malignant and also speak of the poor prognosis of cancer of the breast in women under the age of 35.

It has been our experience that malignancy of the breast in young women is more virulent especially if complicated with pregnancy or lactation.

Table A shows the ages, marital station, lactation history of injury treatment, section and results of treatment of our 25 cases. The Group I cases are those in which the tumor was confined to the breast. Group II, with metastases in the axilla or ulceration of the skin. Group III tumor in the breast which is fixed to the chest wall or ulcerating with wide spread metastases. All the postoperative, recurrent cases in Group III, had widespread metastases at the time of admission.

FEMALE GENERATIVE ORGANS

The gynecological malignancies have been reported in detail by the authors (13)

There were 115 patients 30 years of age or younger suffering from malignancy of the female generative organs 78 epitheliomata of the cervix, 1 adenocarcinoma of the cervical canal 1 adenocarcinoma and epithelioma of the cervical canal 23 malignant tumors of the ovary 1 adenocarcinoma of the fundus of the uterus 1 malignant leiomyomata of the uterus, 2 chorionic epitheliomata of the uterus 3 epitheliomata of the vagina, 1 botryoid sarcoma of the vagina 3 epitheliomata of the vulva.

Table XII shows the ages and marital status of the patients in this group.

If seen early there is a good possibility of eradicating epithelioma of the cervix. The recognition of the disease in its early stage, especially in young women, is important, as it may be the means of saving the life of a young mother so needed for her children's sake. It will be found that cancer prevention in this particular group lies within the grasp of the family physician, who should acquaint himself with evidences of cervicitis, ulcerations, erosions, and leucoplacic areas on the cervix so that he may advise proper treatment for these precursors of malignancy. Abnormal discharges in young women are indications of pathological conditions. Blood as a symptom must be looked upon as accidental—yellow

ish, watery, or foul smelling discharge usually precedes the showing of blood, which does not occur until the tumor begins to ulcerate and break down. Our only hope of discovering and treating early lesions of the cervix lies in careful gynecological examination bimanually and with a speculum resorting to biopsy and cauterization in the so called cervicitis and erosion to rule out or discover early malignancy.

Cervical cancer in young women here reported in Groups I and II (Schmitz) have yielded healings in about the same proportion as the general average in cancer of the cervix namely 50 and 33 per cent. Groups III and IV have been only palliative. All treatment has been by 200 kilovolt X rays externally and radon seeds and radium tubes intra uterine.

Only 1 patient in this group under 30 suffering from epithelioma of the cervix, was unmarried. The 77 others had from 1 to 8 pregnancies, bearing out the theory that trauma and inflammatory lesions have a great influence in the production of malignancy of the cervix.

The only hope in the treatment of ovarian malignancy lies in the early recognition of the disease, and its early treatment by operation and irradiation. The 23 malignant tumors of the ovary include 6 papillary cyst adenocarcinomata, 6 adenocarcinomata, 9 carcinomata, 1 sarcoma, and 1 malignant teratoma. Thirteen of these patients were single, and 10 were married.

Of the 23 cases, only 2 were not proved pathologically, 1 had no operation and the other had had a laparotomy but no section was taken. The majority of these patients had been operated upon before admission. One patient was not treated, the others received either 200 kilovolt X rays or 4 gram radium pack treatment. Six of the patients have lived from 5 months to 8 years after treatment and have been free from the disease for 5 months 6 months, 2 years 2 months, 2 years 8 months, 2 years 10 months and 4 years respectively. This latter patient is alive 8 years since the time of admission but suffered a recurrence 4 years 4 months after original treatment and then was operated on and treated again. Three others are living but are not free from the disease, 2 for over a year with some palliation, and 1 for 2 months unimproved. Three were lost trace of and the 10 others died, 7 in less than a year, 2 in 1 to 2 years, and 1 in 5 years 11 months.

The case of adenocarcinoma of the uterus in a 30 year old patient, was treated with intra uterine radium application and 200 kilovolt X rays over the pelvis. The patient was lost trace of 1 month after treatment.

There were 2 cases of malignant leiomyomata.

One occurred in a patient aged 24, married, whose menstrual periods from the age of 14 were regular but rather profuse, lasting from 7 to 8 days. She had had one miscarriage but no other pregnancies. Seven weeks before admission menstrual periods

TABLE XIII—AGE AND SEX—KIDNEY MALIGNANCIES

Adenocarcinoma									
Mixed tumor									
Embryonal adenocarcinoma									

became longer and harder. Hysterectomy was performed for a supposed fibroid uterus. Pathological examination showed this tumor to be a malignant leiomyoma. This patient received 200-kilovolt X-ray treatments 1 month following operation and was alive without recurrence 5 years and 6 months after treatment when last examined.

The other case occurred in a patient aged 24 years married with 6 children.

This woman had given birth to a child 6 months previous to admission, following which she had a 6 day hemorrhage. Four months after the birth of the child, a hysterectomy was performed for a malignant leiomyoma. At the time of admission there was a recurrence in the vault of the vagina extending into the broad ligament areas. She was treated by radium applications but the lesions progressed and she died without any palliation 9 months later. Autopsy showed recurrence in the pelvis and generalized metastases.

One case of chorionic epithelioma was observed in a patient aged 30 years married a mother of two children aged 8 and 5 years.

Her menstrual periods from the age of 15 were always irregular. At the age of 20, she began to have a yellowish discharge, and for 3 months previous to admission she had continual bleeding following a miscarriage. A pan-hysterectomy was performed and sections from the body of the uterus showed the presence of a chorionic epithelioma. Postoperative irradiation was given and this patient is alive and well 14 years after admission.

The second case of chorionic epithelioma, occurring in an 18 year old female was found at autopsy.

This patient had been treated at the institute for a salivary tumor inner right cheek, was single and gave no history of menstrual disturbance or pregnancy. She was operated on for a "ruptured ovarian cyst" 2 months before admission.

Three cases of epithelioma of the vagina were observed in patients aged 30, and one in a patient aged 28.

One patient, aged 30, gave a history of bearing down pain for 7 months, last menstrual period 3 months previous to admission. She was 3 months pregnant at the time her family physician excised a growth, section of which showed it to be an epithelioma. There was a recurrence of this lesion within a month. Upon admission, the recurring tumor was implanted with gold seeds of radon, following which there was a prompt regression of the tumor. The pregnancy proceeded uninterrupted to full term when a healthy child was born. On last examination, there was no evidence of recurrence, 14 months after treatment.

This case typifies the necessity of prompt and accurate treatment which in this case was successfully performed and was not only the means of saving the life of a mother up to the present time but also the life of a child, conceived before radiation treatment.

One was in a syphilitic, aged 28, who gave a history of continuous bloody discharge only over a period of 3 months. The lesion was far advanced and involved the anterior and lateral walls of the vagina. She was treated by irradiation, which proved of little benefit, and she succumbed to the disease 9 months after admission.

The other also was a far advanced case.

This patient's periods were irregular occurring every 2 weeks and she complained of a yellowish discharge between her supposed menstrual periods. At the time of examination there was a large infiltrating growth involving the posterior wall of the vagina and extending into the posterior fornix. She was treated by irradiation but succumbed to the disease in 2 months.

The botryoid sarcoma of the vagina occurred in a child 2 years of age.

About six months prior to admission the mother had noticed a swelling in the lower abdomen but the child complained of no pain. Following this a growth was found protruding from the vagina and involving the vulva. Part of the growth was removed by her family physician. At the time of examination at the institute, there was a tumor mass in the lower abdomen extending to the umbilicus and a purulent dis-

charge from the vagina. There was a fungating tumor mass involving the vagina and vulva. Sections from this growth showed it to be myxofibrosarcoma, or sarcoma botryoid. The child died of the disease 4 months after irradiation was administered and 10 months from the beginning of symptoms.

Ewing says "Rhabdomyoma uteri appears almost exclusively as an element in the polypoid vaginal sarcoma of children and adults (sarcoma, botryoid, Pfannenstiel). This process affects the vagina in children and chiefly the cervix in adults (Gow and Pick). The symptoms are hemorrhage, fetid discharge, and a protrusion of a polypoid tumor from the vagina, with dysuria, pain, fever and cachexia. The vagina is eventually filled with ulcerating masses and there are bulky extensions into the pelvis. The usual histology is that of a large spindle-cell sarcoma with many blood and lymph vessels, myxomatous tendencies and areas of striated muscle."

Three cases of epithelioma of the vulva were observed, one in a patient aged 25, and 2 in patients aged 30.

The patient aged 25 was single and gave a history of having a small nodule which occurred in theitoris 1 year prior to admission. At the time of examination there was an exceedingly painful, ulcerating tumor about 3 centimeters in diameter which involved the region of theitoris and there were palpable inguinal and femoral nodes. The lesion was treated by irradiation with temporary improvement. During the course of one year the disease progressed and she finally succumbed to extensive involvement of the whole vulva and inguinal lymph nodes.

In this particular case the use of strong douches of bichloride of mercury may have been an etiological factor.

One of the patients, aged 30, was married. Ten months before admission she noticed a small sore on the labia. She consulted a physician who told her it was an ingrown hair and removed it. As she did not get any relief she consulted another physician but with no better results. Later as she was 5 months pregnant, she went to still another physician who told her the sore would probably improve after childbirth. At the time of admission to the Institute the baby was 8 weeks old and the soreness had increased. Examination showed an ulcerating infiltrating epithelioma involving the whole vulva and clitoris region and large metastatic nodes in both groins. Irradiation in this case was of little or no avail and she died in 4 months.

Here, included in this history, is evidence of neglect on the part of the physician to render prompt and efficient treatment.

The other patient, aged 30 years, was single. The lesion had recurred after operation and was far advanced at the time of admission. It was ulcerated and involved the whole vulva. The treatment was irradiation for palliative effect but she died in 6 months.

GENITO-URINARY TRACT

There were 36 malignancies of the genito-urinary tract in patients under 30 years of age. Three adenosarcomata, 4 mixed tumors and 1 embryonal adenocarcinoma of the kidney, 1 congenital sarcoma of the adrenal, 3 epitheliomata of the penis, 24 malignant teratomata of the testicle.

The kidney tumors were all treated with external irradiation either radium packs or 200 kilovolt X rays. Four of these cases had had removal of the kidney before admission and 1 an exploratory operation in which the tumor was too far advanced for removal. All patients except the one suffering from the embryonal adenocarcinoma died in less than 2 months from the time of admission. This patient lived for 1 year 2 months but succumbed from progression of the disease at that time.

Table XIII shows the ages and sex of the patients with kidney malignancies under the age of 30.

The congenital sarcoma of the adrenal occurred in a $2\frac{1}{4}$ year old male and was treated with 200 kilovolt X rays. He died in 2 months and autopsy showed metastases to the liver and lungs.

Malignant tumors of the testicle represent about 0.05 per cent of the total number of malignancies admitted to the Institute. Twenty-four of these occurred at the age of 30 or younger or 43 per cent of the total number of testicular tumors. All of these cases were regarded as malignant teratomata which were divided as follows: 4 adult type, 12 solid embryonal carcinomata, 1 embryonal carcinoma with lymphoid stroma, 6 embryonal adenocarcinomata, and 1 unclassified (no section).

Table XIV shows the ages at which the testicular tumors of different types occurred.

He was treated by amputation of the penis and low power X ray and has been clinically well for 12 years 8 months.

The 28 year old patient was admitted 6 months after he noticed a lump in the groin. This metastatic growth in the groin had been removed and he was circumcised before admission. Upon admission he was treated with 200 kilovolt X rays. He died in 3 months.

MISCELLANEOUS

There was 1 case of carcinoma in the sacral region in a 30 year old female. Although biopsy showed carcinoma, we believe this may have been a malignant teratoma. Four months before admission this patient noticed severe pain and swelling of the hip. She was treated with the radium pack and died 5 months after admission from progression of the disease.

Another case, in a 30 year old male was an adenocarcinoma of the left scapula. The growth had been removed at the time of admission, he was treated with 200 kilovolt X rays, did not improve, and was lost trace of in 3 months.

Another was a metastatic carcinoma of the neck in a 29 year old male. The primary source was not ascertained. He was treated with 200 kilovolt X rays and died in 3 months.

There were 6 cases of endothelioma. 3 in the lymph nodes in the neck, 2 in the thigh with metastases in the groin, and 1 in the soft tissues over the hip in 7, 12, 14, 15, 21 and 29 year old patients, 2 males, 4 females. All had histological sections, were treated with 200 kilovolt X rays and died in from 5 to 9 months from the time of admission from generalized metastases.

BONE

There were 48 primary bone sarcomata in patients under 30 years of age. 36 osteogenic sarcomata (including 1 sclerosing type, 2 peritheliomata, 1 myxofibrosarcoma), 3 osteochondrosarcomata, 3 chondrosarcomata, 1 hereditary deforming chondrodysplasia with secondary chondrosarcoma of the femur 5 Ewing sarcomata.

The 36 osteogenic sarcomata involved the upper extremities in 9 patients (8 humerus, 1 forearm), the axilla in 1 patient, the lower extremities in 19 patients (12 femur, 4 tibia, 1 fibula and 2 foot), the ischium in 1 patient,

the ilium in 1 patient, the supra-orbital ridge in 1 patient, and the lower jaw in 4 patients. All of these tumors were far advanced on admission, 6 patients having metastases in the lungs in addition.

In 6 cases the extremity was amputated and treated by irradiation, either 200 kilovolt X rays or radium packs. Four of these patients died 1 in 9 months, 1 in 1 year, 1 in 1 year 3 months, and 1 in 2 years, from metastases to the lungs, no recurrence on the stump.

One patient was lost trace of in 1 year 6 months at which time he wrote he was feeling well, the other died 11 months after amputation from pulmonary tuberculosis, no recurrence of the malignancy at the time of death.

In one case the tumor was removed from the right tibia followed by irradiation and this patient is now clinically well 1 year 6 months since admission.

Sixteen other cases in which the tumor involved the extremity were treated by irradiation only. Thirteen died in less than a year and 3 died in from 1 to 2 years.

In 1 case the tumor in the os calcis was removed surgically and then treated by radiation. The growth was arrested for 4 years when a bluish-looking tumor developed in the scar over the skin of the foot where it was irritated by the patient's shoe. This grew with a sudden rapidity necessitating amputation of the leg. Patient was 6 months pregnant at the time of amputation and a normal child was born 5 months before her death from general metastases to the lungs and viscera 8 years 5 months after admission.

The sclerosing osteogenic sarcoma of the humerus which was treated by irradiation only has been arrested for 3 years.

One of the peritheliomata occurred in the fibula, was treated by means of the radium pack and then the leg was amputated elsewhere. The patient died 2 years after amputation.

The perithelioma in the femur was treated with 200 kilovolt X rays and the patient died 9 months after admission from progression of the lesion and metastases to the lungs.

The tumor in the axilla was removed surgically and histologically showed osteogenic sarcoma. The patient was then subjected to irradiation and has been clinically well for 2 years 4 months. This was a case of osteosarcoma in soft tissue but with no involvement of bone.

The osteogenic sarcoma of the ischium had metastasized to the lungs and pelvis at the time of admission. This was treated with irradiation but the patient died in 1 month.

The tumor in the ilium also was treated by irradiation and is now progressing 8 months after admission.

The sarcoma in the supra-orbital ridge was incised and some of the tumor tissue removed. It was then

TABLE VI—AGE AND SEX INCIDENCE IN BONE MALIGNANCIES

treated by irradiation but the tumor progressed and the patient died in 1 year 11 months.

Two of the jaw tumors were treated by irradiation only. 1 patient died in 3 months and 1 in 5 months. One patient is living for 6 years with arrest of the tumor following biopsy and irradiation. One tumor was excised and the patient then subjected to irradiation. This patient died in 7 months.

The symptoms in these cases were pain and swelling. Twenty-two patients gave a history of injury as the beginning of their illness. 8 fell striking the diseased part, 7 gave a history of muscle strain, 6 a blow and 1 of being burned by the explosion of fire-works.

One of the osteochondrosarcoma occurred in the humerus. This was treated by irradiation. The tumor process had apparently been arrested but was still present at the time of death from other causes 5 years 8 months after admission.

The second osteochondrosarcoma occurred in the femur. This was treated by irradiation and the patient died in 3 months.

The third tumor occurred in the sacrum. The tumor was removed and then the patient was irradiated, and died in 9 months. There was a history of injury in 1 case.

The three chondrosarcoma occurred in the sacroiliac region, sixth rib and the tibia. All were treated with 200 kilovolt X rays and died in 3 months, 5 months, and 8 months respectively. There was a history of injury in 2 cases.

The hereditary deforming chondrodysplasia with the secondary chondrosarcoma of the femur occurred in an 18 year old boy. This was treated by irradiation and amputation of the femur was advised but refused. The lesion is rapidly progressing now 1 year 8 months after admission.

The five Ewing sarcoma occurred in 7, 11, 12, 14, and 15 year old children. 3 in the tibia, 1 in the femur and 1 in the ischium. Four

of them had a history of injury at the site of the tumor.

One patient with a tumor in the tibia had the tumor removed by curettage and was then treated with 200 kilovolt X rays. This child was clinically well for 2 years 11 months when there was a recurrence and she died 3 years 4 months after admission from generalized metastases.

Another patient with a lesion in the tibia was treated with irradiation and then the leg was amputated. He lived 2 years 2 months when he died from lung metastases.

The third patient with the tumor involving the tibia died in 3 months. He also was treated with 200 kilovolt X rays.

The patient with the tumor in the femur died months after admission. There was some local improvement following X ray treatment.

The fifth case, with the tumor in the ischium, is still alive 1 year 7 months after admission and has shown some local improvement following 200 kilovolt X ray treatment.

MISCELLANEOUS SARCOMATA

There were 72 cases of miscellaneous sarcomata, not included in any of the foregoing groups of cases reported in this paper. Twenty-six were lymphosarcomata, 4 wherein the biopsy showed lymphosarcoma but the blood pictures were that of aleucemic leukemia, 4 angiosarcomata, 2 mixed cell sarcomata, 6 fibrosarcomata, 3 myxofibrosarcomata, 15 spindle cell sarcomata, 8 neurofibrosarcomata, and 4 unclassified sarcomata, as follows:

There were 26 cases of lymphosarcoma in patients under 30 years of age: 18 males and 8 females.

Nearly all of these patients gave the history of a painless swelling; only 2 gave the history

of any pain as the beginning of their illness. In 17 cases the duration was less than 6 months, in 7 cases for 1 year each, and 2 cases for 3 years each. All of these growths developed rapidly. Twelve were noticed first in the neck, 1 in the parietal region, 2 over the scapula, 1 in the axilla, 1 in the forearm, 4 in the abdominal nodes, and 5 were lymphosarcomatous primary source unknown. With one exception—a leucocyte count of 26,600—the original leucocyte counts varied from 7,000 to 18,900. In only 4 instances did the percentage of lymphocytes exceed 30.

One case in this group was not treated. The others were treated by 200 kilovolt X rays in 23 cases and radium packs in 2 cases. In all of them there was marked regression of the tumors immediately following treatment but 23 patients died from progressive anemia and general lymphosarcomatosis, 1 in 1 month, 6 in 2 months, 5 in 3 months, 5 in 4 months, 1 in 5 months, 1 in 6 months, 1 in 10 months, 2 in 1 year, and 1 in 2 years, 6 months. One patient is living for 7 months since treatment and another is living for 3 years 7 months but is still undergoing treatment from time to time.

There were 4 cases in which the biopsy showed lymphosarcoma but the blood pictures in all assumed that of an aleukemic leukemia, the lymphocytes varying from 52 to 76 per cent.

The disease occurred in a 23 year old female who died in 2 weeks following 200 kilovolt X rays, a 13 year old male who also died 2 weeks after admission, an 11 year old male who is living 7 years after admission who was irradiated and is well 5 years since last treatment, and a 23 year old male who is living 5 years after admission and is clinically well for 1 year since last treatment.

There were 4 cases of angiosarcoma

One occurred on the cheek of a 5 year old female. This was removed surgically and treated prophylactically with a large amount of radon lightly filtered, and the patient has remained clinically well for 11 years.

The next case of angiosarcoma occurred in an 11 year old female. This child's trouble began with abscesses on the vulva following an injury in the gymnasium after which a mass developed in the pelvis. Upon admission she had a generalized sarcomatosis. She was treated with 200 kilovolt X rays

following which there was relief of pain and she gained some strength for a time. She died 8 months after admission and autopsy showed angiosarcoma involving the pelvis, lungs, ribs, bronchial glands, scalp, extradural space, brain, and tissues about the spine.

The third case occurred in a 25 year old male in the tissue over the right scapular region. Following 200 kilovolt X rays over this area the tumor disappeared but the patient developed lung metastases and died 4 months after admission.

The fourth case occurred over the ankle in a 21 year old female. She was treated with radium packs with marked regression of the tumor. She was delivered of a normal child 10 months after admission. During the latter months of her pregnancy and following her delivery she was unable to report for observation or treatment. The lesion progressed and the leg was amputated at another hospital. Five months later there are numerous and widespread metastases and patient is moribund.

Three of these patients gave a history of injury as the beginning of their illness.

There were 2 cases of mixed cell sarcoma, 1 on the foot of a 24 year old male and one in the thigh of a 30 year old female.

The lesion in the 24 year old male had existed 5 years previous to admission, appearing as a swelling which followed an injury caused by dropping a sharp plank on his foot. This swelling grew gradually until 9 months before admission to the institute, after which it grew rapidly. It was excised 1 week before admission. The scar was treated with low power filtered X ray and appeared clinically well for 1 year 10 months when there was a recurrence. Three years after admission lung metastases developed and the patient died; the lesion on the foot was not healed at the time of death.

The lesion in the 30 year old female began as a hard lump on the thigh $1\frac{1}{2}$ years before admission. This remained stationary for 2 years after which it began to grow rapidly. The growth had been removed about 3 weeks before admission. Upon admission, the incision was nearly healed and she was treated prophylactically with 200 kilovolt X rays. There has been no recurrence up to the present time, years 5 months after admission.

There were 6 cases of fibrosarcoma. These lesions occurred 1 on the top of the head, 1 over the eyebrow, 1 at the angle of the jaw, involving the bone, 1 over the shoulder, 1 in the thigh, and 1 in the abdominal wall. Two of these patients gave a history of injury as the beginning of their present illness. In all the cases the tumors were removed and treated with 200 kilovolt X rays. Three of

TABLE XVI—AGE AND SEX INCIDENCE—SARCOMA EXCLUSIVE OF BONE SARCOMA

the patients are clinically well since treatment 1 for 5 years 1 for 1 year and 1 for 7 months.

In 1 case the tumor has remained stationary since the time of admission, 1 year 2 months. The patient with the skull lesion died in 3½ months and autopsy showed fibrosarcoma involving the dura mater.

The patient in which the jaw bone was involved died 1 year 3 months after admission from progression of the disease.

There were 4 cases of *myofibrosarcoma*. Two of these patients gave a history of injury as the beginning of their trouble.

One of these lesions occurred in the ischioanal space of a 17 months old female. The tumor was removed and treated with radium. She has been clinically well for 3 years without recurrence. One occurred over the sacrum of a 6 year old female, was removed surgically and treated with 200 kilovolt X rays and has been clinically well for 4 months following last treatment. It is now 7 months since admission.

The third occurred in a 20 year old female, at the knee. This was treated with the radium packs with no improvement. The leg was amputated elsewhere and the patient died 8 months after admission to our hospital from metastases into the chest.

The fourth case was in the arm of a 29 year old female. This patient also had a carcinoma of the left breast which is reported in this paper with the breast lesions. The breast lesion was treated at our institution but at the time of admission, the arm had been amputated by shoulder girdle amputation. Sections of the lesion showed no bone formation. There has been no recurrence of the sarcoma for 10 years.

There were 15 cases of *spindle cell sarcoma* 1 of the jaw 1 mastoid region 1 frontal region

3 arm 2 axilla, 2 shoulder 4 lumbar region and 1 foot. Five patients gave a history of injury as the beginning of their present illness. One patient was not treated. The others were treated by the removal of the tumor followed by irradiation either 200 kilovolt X rays or radium packs. Eight of the patients died from the disease 6 in less than a year 1 in 12 years, and 1 in over 6 years.

The patient who died 12 years after admission was clinically well for 9 years when there was a recurrence which responded to further treatment and the local lesion was well at the time of death from liver and lung metastases.

The patient who died 6 years 2 months after admission died from metastases to the lungs and axilla, the lesion in the arm did not recur and had been clinically well for 4 years 4 months before death from metastases. Five of the patients are clinically well 3 for 14 years, 2 for 2 years, and 1 for 1 year. The other patient has been having palliation since admission, 8 months ago.

There were 8 cases of *neurofibrosarcoma*. Three of the patients gave a history of injury at the site of the lesion previous to noticing the lesion. In 7 of the cases, the tumor was removed and irradiation treatment either 200 kilovolt X rays or radium pack, was given.

In 1 case irradiation only was given by means of 200 kilovolt X rays. This patient died 10 months after admission from rapid extension of the lesion throughout the abdomen.

The others have been clinically well 1 for 10 years 1 for 3 years, 2 for over 2 years, 2 for over 1 year and 1 has been receiving treatment over a period of 4 years. There is no progression of the disease in the latter case but nodules are still present.

There were 3 cases of *unclassified sarcoma*

One occurred in a 10 month old female following injury. The tumor involved the left temporal region and orbit, was hard and seemed attached to the bone but X ray plates showed no destruction of bone. Section was taken but this tumor could not be definitely classified. Treatment was by means of 200 kilovolt X rays. She died 2 years 3 months after admission from sarcomatosis.

One occurred in the soft tissues of the hand of a 15 year old girl and the metacarpal bones were involved secondarily. Treatment was by means of the radium packs. Marked regression of the tumor followed. Sixteen months after admission, the patient died from mediastinal and lung metastases.

The third case occurred in the right thigh of a 22 year old female. This tumor was removed surgically and then treated with 200 kilovolt X rays. It is now 5 months since admission and there is no recurrence since treatment.

Table XVI shows the ages and sex of the sarcomata, excluding the bone sarcomata

HODGKIN'S DISEASE

The total number of cases of Hodgkin's disease admitted to the institute up to October 1, 1933 was 137, 64 of these were in patients 30 years of age or younger as shown in Table XVII, 39 males and 25 females.

Hodgkin's disease is a disease of the reticulo-endothelial system which is looked upon by some authorities as an infectious granuloma and by others at least at times as of distinct neoplastic origin namely Hodgkin's sarcoma (Ewing). Hodgkin's disease may occur at any age, 47 per cent of our cases occurred before the age of 30. It is characterized by a large variety of symptoms. Zeigler, as quoted by Ewing, recognized an acute or chronic form. The duration varies from a few weeks in acute cases to many years, but is usually about 18 months. In this disease the origin may be in the lymph nodes anywhere in the body but frequently in the beginning involves the cervical, axillary inguinal, mediastinal or abdominal nodes. Eventually most cases show a generalized involvement, progressive anaemia, chlorotic type or even sometimes assuming a pernicious type. In our experience blood examinations showed loss of haemoglobin and red blood cells the leucocytes varied from 2,500 to 128,000 but, contrary to some authors, lymphocytosis or eosinophilia

was rarely observed. An intense pruritus is frequently associated with Hodgkin's disease early as well as late. Fever may be present early but is usually associated with the terminal stages.

From the diagnostic point of view, the enlargement of the cervical chain, axilla, or inguinal nodes, which are painless, hard, and often associated with considerable fibrosis, are common clinical findings. Biopsy is essential in the diagnosis of Hodgkin's disease.

Irradiation in Hodgkin's disease is of distinct palliative value and is in all probability the best form of therapy today. The prognosis is always grave. The majority of patients suffering from this disease succumb before the end of 3 years.

Of the 64 cases of Hodgkin's disease in patients under 30 years of age 5 were not treated, the 59 others were treated with 200 kilovolt X rays with the following results: Forty-eight patients died 21 in less than a year 14 in 1 to 2 years 7 in 2 to 3 years, 2 in 3 to 4 years 3 in 5 to 6 years, 1 in 6 to 7 years. Three were lost trace of 1 after having palliation for 2 years 1 after being clinically well for 1 year 5 months, 1 who was unimproved after treatment for 1 year. Eight are still alive 1 for 4 years but is now in the terminal stages of the disease 1 for 3 years 4 months, feeling well, 1 for 1 year 9 months who is having palliation 5 for less than a year since admission 2 are having palliation for 10 months and 11 months, respectively and 3 are not improving.

Thirty-one cases are available for 5 year statistics 4 or 12.8 per cent lived 5 years or more. Thirty nine cases are available for 3 year statistics of which 8 or 20 per cent have lived 3 years or more.

TABLE XVIII—LEUCÆMIA, AGES

Age	2	10	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30
Lymphatic leucæmia																			
Chloroma																			
Myelogenous leucæmia																			

LEUCÆMIA

There were 20 cases of leucæmia in patients under 30 years of age: 11 lymphatic leucæmias, 1 chloroma, and 8 myelogenous leucæmias (See also under lymphosarcomata 4 cases with aleucæmic blood pictures.)

Table XVIII shows the ages of these patients: 11 males 7 females.

The patients suffering from lymphatic leucæmia complained of weakness, loss of weight, pain in various parts of the body and epistaxis. The majority of these patients suffered from their symptoms for only a few months. Upon examination there was found enlargement of the cervical axillary and inguinal nodes and enlargement of the spleen and liver. The original counts showed the hæmoglobin ranged from 10 to 70 per cent, red blood count from 604,000 to 5,020,000, leucocyte count from 29,000 to 525,000, lymphocytes from 79 to 98 per cent. Under X-ray treatment a marked drop in leucocyte counts was noted. All of the patients in this group died within 6 weeks after admission. Six of the cases came to autopsy with the usual findings of a lymphatic leucæmia.

X-ray treatments were given according to the total leucocyte count and the patient's general physical condition: doses of 25 to 40 per cent at 200 kilovolts. Patients were not treated if the total leucocyte fell below 30,000. Even in spite of this precaution in a few instances, the reduction in the total leucocyte count continued until they showed a decided leucopenia.

The chloroma occurred in a 5 year old female.

Her blood count on admission was: hæmoglobin (Sahl) 70 per cent, red blood count 3,776,000, leucocyte count 27,000, myelocyte 1 per cent, polymorphonuclears 63 per cent, lymphocytes 30 per cent, monocytes 6 per cent. Following treatment with 200 kilovolt X-rays over the orbit, lumbar and sacral regions, the leucocyte count went down to 17,000 with a differential count of 64 per cent polymor-

phonuclears, 22 per cent small lymphocytes, 14 per cent large lymphocytes, and the patient was much improved for almost 3 months when the symptoms recurred and she succumbed to the disease 4 months after she was admitted to the hospital.

The patients suffering from myelogenous leucæmia complained of the same symptoms except that most of them noticed enlargement of the abdomen and the duration of their symptoms was for a longer period of time: that is, from 6 months to 1 year and 10 months.

The original leucocyte counts ranged from 140,000 to 332,000. Following irradiation with 200 kilovolt X-rays there was a reduction in the total leucocyte counts and reduction in the size of the spleen. These patients were not irradiated if their general condition did not warrant it or if the total leucocyte count was below 30,000.

One of the patients died in 23 days from intestinal hemorrhage. The others lived from 5 months to 21 months. One patient is still alive 1 year after admission. At present the spleen is markedly enlarged and the leucocyte count is 187,000, although at one time it was as low as 12,600.

Two of these patients came to autopsy with the usual findings of myelogenous leucæmia.

A STUDY OF THE ACTION OF ERGOT ON THE HUMAN PUERPERAL UTERUS¹

ARTHUR K. KOFF, M.D., CHICAGO

From the Johns Hopkins University Department of Obstetrics, Baltimore, Maryland

THE uncertainty concerning the therapeutic effects of various ergot preparations on the human uterus has led some clinicians to question their clinical value. A number of factors contribute to this uncertainty. The nature of the active principles of ergot has been the source of much controversy during recent years. It follows, therefore, that since the active elements have not been conclusively established, the standardization of activity is difficult. This difficulty is increased by the fact that uteri in different physiological states of the same species, and in the same physiological states in different species often give divergent results with the same agent. Again findings *in vitro* and *in vivo* do not always correspond. It is obvious that the most desirable form of confirmation of experimental findings lies in their clinical applicability. The following study was undertaken in order to investigate the relative clinical value of various ergot preparations.

A study of its history shows that ergot has some oxytocic effect on the human uterus. It was first described in Adam Lonicer's *Kreuter buch* published in 1582 where it was mentioned as a proved means of inducing pains of the womb. In the 17th and 18th centuries midwives in most of the European countries used homemade preparations of ergot to stimulate labor pains. However it was not introduced into official medicine until the early part of the 19th century. In 1808 there appeared in *The Medical Repository of New York* an account of Pulvis Parturientis, a remedy for quickening childbirth. This was published in the form of a letter from Dr. John Stearns, then a practitioner in Saratoga County, New York. Four years later Dr. Oliver Prescott of Boston read a Dissertation on the Natural History and Medicinal Effects of Ergot. Subsequently ergot was used widely by physicians in this country to stimulate labor and to control postpartum

hemorrhage. Today of course the dangers of administering ergot before the termination of labor are well known and its use during this process has fallen into disrepute.

The original edition of the U. S. *Pharmacopoeia* in 1820 was the first official publication to admit ergot as a drug. Since this time a large amount of chemical and pharmacological work has been done to determine the nature of its active principles. It has been generally accepted that the activity of ergot lies in the alkaloidal fraction. Alkaloids were first shown to be present by Wenzell in 1864, but none was obtained in a state of purity until Tanret, in 1876, crystallized ergotinine, which proved to be practically inactive. Barger and Carr in 1906 isolated an alkaloid in the form of a crystalline salt, named ergotoxine. In the same year Kraft showed this alkaloid to be a hydrate of the ergotinine described by Tanret. Ergotoxine was investigated by Barger and Dale who believed it to be the active principle of ergot because of its ability to stimulate smooth muscle, and particularly uterine muscle, of the experimental animals used. Stoll in 1918 discovered a third alkaloid, ergotamine, which has a physiological activity indistinguishable from ergotoxine (Dale and Spiro 1922; Moir 1932). Until recently both ergotoxine and ergotamine were generally recognized as the active oxytocic principles of ergot. Still another ergot alkaloid, sensibamine, has recently been placed on the market as an oxytocic.

Much interest was aroused when Moir in 1932, working on the human puerperal uterus, found that aqueous ergot preparations, such as the fluid extract of the British *Pharmacopoeia*, showed an oxytocic effect far out of proportion to the amount of ergotoxine and ergotamine present. This interested us in particular since we have been using both aqueous and alcoholic preparations of ergot with apparently equally good clinical results.

¹Author is at present connected with the Department of Obstetrics and Gynecology, University of Chicago.

Fig. 1. Diagram of apparatus used showing position of hydrostatic bag in uterus. Stilette prevents bag from slipping down into cervix.

When assayed for the specific alkaloids by the Broom-Clark method, the aqueous preparation, ergotole, contained not over 0.15 milligrams per cubic centimeter while the alcoholic preparation, fluid extract of ergot U.S.P. contained over 0.5 milligrams per cubic centimeter both in terms of ergotoxine as a standard.

A review of the literature shows that the accuracy of conclusions drawn from clinical observations on the efficacy of these ergot preparations is subject to doubt. Therefore it was decided to determine by a more direct method the relative oxytocic value of an aqueous extract (ergotole), U.S.P. fluid extract of ergot and various other ergot preparations containing the isolated and presumably active alkaloids ergotoxine, ergotamine sensibamin

METHOD AND MATERIAL

The experiments were performed during the normal puerperium on patients who had had short uncomplicated labors and afebrile postpartum courses. This group of cases was chosen for two reasons: first because ergot preparations are used mainly during the puerperium, and second because there was less danger of infecting the patient. In order to make results more comparable each experiment was performed on the fifth or sixth day of the puerperium and at least 2 hours after the intake of food. A modification of the

method described by Bourne and Burn in 1927 and further elaborated by Moir in 1932, was used. A sterilized watch-shaped rubber bag was introduced through the cervix into the uterus by means of a stilette. The bag was connected by lead tubing to a mercury manometer which was fitted with a float and marker for recording contractions on a revolving smoked drum. The bag was inflated with water to a pressure equivalent to 20 millimeters of mercury (Fig. 1).

Sixty-two satisfactory experiments have been executed and the following preparations have been tested in the stated number of cases:

- 1 Fluid extract of ergot U.S.P.—10 cases
- 2 Ergotole—8 cases
- 3 Ergotamine tartrate—10 cases
- 4 Ergotoxine ethane sulphonate—8 cases
- 5 Ernutin (a preparation which contains histamine, tyramine and ergotoxine) 3 cases
- 6 Histamine—4 cases
- 7 Sensibamin—6 cases.
- 8 An ergot preparation¹ from which all the alkaloids were removed—4 cases.
- 9 A preparation¹ which contained all the alkaloids of ergot—4 cases
- 10 A preparation¹ containing the alkaloids of ergot except ergotoxine—2 cases

¹Prepared by Professor Marvin R. Thompson, Department of Pharmacology, University of Maryland. The pharmacology and chemistry of these preparations is being reported elsewhere by Dr. Thompson.

Fig. 2. Fluid extract of ergot USP 1 cubic centimeter (equivalent to 0.5 milligram specific alkaloids by assay). Oral administration. Onset of contractions in 5½ minutes. Rise above base line indicated slight tonic. Regular and intermittent contractions lasted over 2 hours.

Fig. 3. Fluid extract of ergot USP 4 cubic centimeters (equivalent to 3.0 milligrams specific alkaloid by assay). Oral administration. Contractions began in 6 minutes. Rise above base line indicated sustained tonic contractions. This is typical fluid extract curve. Duration of tetany 1 hour and 50 minutes.

11. A synthetic preparation resembling fluid extract of ergot—3 cases.

In most cases a different patient was used for each test because the long duration of the action of some of these preparations prevented the recording of two experiments on one individual. No 2 patients produced exactly the same type of tracing. One uterus was entirely inactive, another very active. In general, three types of physiological reactions occurred: (1) Very active uteri showed contractions every 2 to 3 minutes. (2) Moderately active uteri showed strong contractions every 15 to 20 minutes. (3) Inactive uteri showed occasional weak contractions or none at all.

The effects of these ergot preparations are illustrated on the inactive uterus only since the results are more comparable. When pos-

sible each ergot preparation was tested by oral, subcutaneous, intramuscular and intra-venous administration.

ORAL ADMINISTRATION OF ERGOT PREPARATIONS

From Figures 2 and 3 it may be seen that fluid extract of ergot standardized to contain 0.5 milligrams per cubic centimeter of specific alkaloids produced the expected degree of oxytocic effect. However, ergotole, (Figs. 4 and 5) an aqueous preparation containing not over 0.15 milligrams per cubic centimeter ($\frac{3}{4}$ the value in terms of specific alkaloidal content) produced almost exactly the same effect from the standpoint of the onset, duration and degree of tonic contractions of the uterus. It is surprising as Moir (1932) pointed out that

Fig. 4. Aqueous extract (ergotole) 1 cubic centimeter (equivalent to 0.15 milligram specific alkaloids by assay). Oral administration. Contractions began in 9 minutes. Absence of rise above base line indicated lack of tonus increase (compare with Fig. 1). Contractions continued for over 2 hours.

Fig. 5. Ergotole 4 cubic centimeters (equivalent to 0.64 milligram specific alkaloids). Oral administration. Contractions began in 14 minutes. Rise above base line indicated sustained tonic contractions. Duration of tetany 1 hour and 6 minutes.

aqueous preparations of ergot which contain very small amounts of the presumably active principles should have an oxytocic effect that is so great. Our experiments have demonstrated that this effect is far out of proportion to the amount of the so called specific alkaloids present in solution (Fig. 6).

The observations recorded in Figures 6, 7, 8 and 9 indicate that ergotamine, ergotoxine, and sensibamin given by mouth, even in large doses, do not exert rapid or great enough oxytocic effect to be of clinical value in obstetrics. This work substantiates the statement of Mour that "Oral administration of ergotoxine and ergotamine even in doses of 2 milligrams did not yield consistent results." We wish to

draw particular attention to Figure 8 which compares the effect of 2 milligrams of the specific alkaloid ergotamine tartrate with that of 4 cubic centimeters of the aqueous preparation (4 cubic centimeters contains 0.64 milligrams of specific alkaloid). Here, the rapid and powerful effect of the aqueous preparation when compared with the absence of any effect from administration of the specific alkaloid is striking evidence that ergotamine is not responsible for the major oxytocic action of ergot.

On the basis of pharmacological investigation it has been generally accepted that ergotoxine or ergotamine was essential for the efficacy of ergot preparations. Preparations

Fig 6 Ergotamine ethane sulphonate, 3 milligrams orally. Onset of contractions occurred in 54 minutes. No sustained rise above the base line indicated lack of toxa increase. Contractions are intermittent and irregular. (Three milligrams of ergotamine is equivalent by assay to 30 cubic centimeters aqueous preparation.) Tracing was continuous but only sections of it are shown as indicated by the record.

Fig 7 Ergotamine tartrate, 6 milligrams orally. Contractions began in 43 minutes. No rise above the base line indicated lack of toxa increase. Duration of contractions was 2 hours. (Six milligrams ergotamine is equivalent to 30 cubic centimeters U S P fluid extract of ergot.)

containing negligible quantities of these alkaloids were therefore considered inert by many authorities. Contrary to this opinion administration of aqueous preparations containing insignificant amounts of the specific alkaloids produces a degree of uterine muscle spasm considerably in excess of that produced by the alkaloids ergotamine, ergotamine and sensibamin. This suggests that ergot may contain a substance hitherto unidentified which is responsible for the major oxytocic effect.

In general it may be said that when given orally in proper dosage (4 cubic centimeters or over) both the aqueous preparation ergotole and U S P fluid extract of ergot produce a rapid and powerful oxytocic effect. On the other hand, the action of ergotamine, ergotamine, and sensibamin by oral administration is so slow and inconsistent that the clinical use of these drugs when given by mouth seems of doubtful value.

INTRAMUSCULAR ADMINISTRATION OF ERGOT PREPARATIONS

It has been possible to obtain consistently good results by intramuscular administration of these alkaloids (ergotamine ethane sulphonate ergotamine tartrate [gynergen] sensibamin) only in doses of 2 milligrams or over (Figs. 10, 11 and 12). In some of these cases, shortly after administration, the patients developed headaches, blurring of vision and nausea, particularly after the administration of ergotamine. The results shown here and the numerous clinical reports on ergotamine and ergotamine leave no doubt that these alkaloids are effective parenterally. Nevertheless, these alkaloids were practically inactive by mouth, and administration by the intramuscular route was often associated with toxic symptoms. These facts render these drugs less valuable and less dependable. The fact that no symptoms occurred when large

Fig. 8 Ergotamine tartrate 2 milligrams orally. No contractions during 1 hour. Four cubic centimeters aqueous ergot given to same patient for comparison of effect. Contractions began in 12 minutes. Marked rise in base line indicating tonic contractions. (Two milligrams ergotamine is equivalent by assay to 13 cubic centimeters aqueous ergot [ergotole].)

Fig. 9 Sensibamin, 4 cubic centimeters (2 milligrams) orally. Contractions began in 30 minutes. No rise in base line. Four cubic centimeters ergotole given as control. Onset of contractions in 6 minutes followed by strong tetany. Only sections of tracings are shown.

doses of ergotoxine and ergotamine were given by mouth would seem to indicate that these alkaloids are probably very slowly absorbed from the intestine. Burn in 1929 estimated that something like 30 per cent is absorbed from the cat's intestine. Nevertheless, taking this into consideration one should obtain better results than those heretofore shown from the large doses administered by mouth.

It has been claimed by some authors (Jaeger 1913) that the oxytocic effect of ergot is due to histamine. Thompson found in a series of 10 ergot samples a percentage of histamine ranging from 0.012 to 0.150. In our experience histamine exerted no oxytocic effect by mouth and only a transitory effect when given intramuscularly as was emphasized by Thompson in 1930 (Fig. 13).

ORAL ADMINISTRATION OF ERGOT FRACTIONS

It is clear from this study that when given orally and subcutaneously aqueous ergot preparations which contain not more than

traces of ergotoxine and ergotamine show an oxytocic effect far out of proportion to the activity exhibited by the specific alkaloids present in the solution. These alkaloids—ergotamine, ergotoxine, sensibilin—are practically inactive by mouth. Moreover they do not stimulate the uterus to the expected pharmacological activity when given by either the intramuscular or intravenous route. This suggests that the action of ergot cannot be entirely due to ergotoxine, ergotamine or sensibilin. In fact it implies the presence of some more active substance, probably water soluble, since aqueous ergot preparations were very active. With this in mind an attempt was made to divide ergot into fractions in order to determine as much as possible the identity of the unknown principle.

Through the courtesy of Dr. Marvin Thompson three fractions¹ were obtained for testing.

The chemical and pharmacological details regarding these fractions were presented before the scientific section, annual meeting of the American Pharmaceutical Association at Washington, D. C., and are in press.

Fig. 10. Ergotamine ethane sulphonate, 2 milligrams intramuscularly. Contractions began in 13 minutes. Rise above the base line indicated increase in tone. Tetany for 34 minutes followed by strong intermittent contractions.

Fig. 11. Ergotamine tartrate (synergen) 2 milligrams intramuscularly. Contractions began in 10 minutes. Contractions at first strong and intermittent followed by a period of tetany lasting 65 minutes.

1. Alkaloid-free fraction containing essentially all extractives of ergot except the total alkaloids (Fig. 14).

2. Total alkaloidal fraction remaining after removal of fraction 1 (Fig. 14).

3. A fraction resulting after the chemical removal of essentially all of the ergotamine, ergotinine and ergotaminine from fraction 2 (Fig. 15).

Each fraction was made up so that the dosage of 1 cubic centimeter was equivalent to its amount in 1 gram of crude ergot.

From Figure 14 it may be seen that the fraction of ergot that did not contain alkaloids was absolutely inactive. Since the alkaloidal fraction did produce as rapid and powerful an effect as that obtained by oral administration

of aqueous and alcoholic whole extracts of ergot one may say unequivocally that the activity of ergot lies in, or is associated with this alkaloidal fraction (Fig. 14). It is probably true that during the process of extraction some of the activity is lost. It is evident, as shown in Figure 15 that even though the ergotamine was removed the remaining alkaloidal fraction had a high degree of activity. As far as we can make out this alkaloidal fraction is responsible for most of the oxytocic action of ergot.

EVALUATION

It is the custom of most obstetricians to prescribe ergot preparations following the third stage of labor in order to produce tonic contractions of the uterus. The objects of

Fig 12. Sensibamin 2 cubic centimeters intramuscularly. Contractions began in 6½ minutes. Strong tetany for 1 hour and 46 minutes.

Fig 13. Histamine 1 milligram intramuscularly. Contractions began in 1½ minutes. Rise in base line indicated tetany which lasted 6 minutes followed by weak, irregular contractions. Comparison of the effect of 4 cubic centimeters opothole on the same patient. Tracing is continuous but only parts are shown.

this treatment are mainly to control immediate and delayed postpartum bleeding to favor involution of the uterus, to diminish the likelihood of postpartum infection by expelling retained lochia. Moreover, in some clinics ergot preparations are given in order to complete abortions in cases in which secundines are retained. Practically all authorities deprecate strongly the use of ergot during any stage of labor, mainly because of the danger of rupture of the uterus and asphyxia to the child due to tetanic contractions of the uterine muscle.

It should be stated here that we consider an oxytocic drug clinically valuable when its action is rapid and consistent, and the contractions tetanic and of long duration. For the control of hemorrhage, rapid action and tetanic contractions are obviously necessary. Any drug that produces only intermittent contractions will allow bleeding to take place during the intervals and is therefore of little value. It is generally stated that drugs which

exert a prolonged and tetanic effect are more desirable in furthering involution. This opinion is probably based on the observation that postpartum uteri involute more rapidly when strongly contracted.

The task of evaluating clinical reports on the merits of various ergot preparations is difficult mainly because a large number of the constituents extractable from the crude drug exert a greater or lesser degree of oxytocic effect. Numerous attempts have been made to isolate the specific or active principles, and on the basis of the pharmacological results on laboratory animals most of these extractives have been given a fair clinical trial. These extractable constituents of ergot were classified by Thompson (1930) as follows:

1. Specific alkaloids such as ergotoxine, ergotinine, ergotamine, and ergotaminine.
2. Non specific amines such as histamine, tyramine, acetyl choline.
3. Inert extractions. These consist of one or more pigments 10 to 35 per cent of fixed

FIG. 14. Fraction 1 (alkaloid free) 10 cubic centimeters orally. There was no stimulation of uterine muscle indicating lack of oxytocic activity. Compare effect of 4 cubic centimeters alkaloidal fraction No. 2. Contractions began in 8 minutes. Strong intermittent contractions with marked rise in the base line indicated uterine muscle spasm.

oil, small amounts of inorganic salts and appreciable quantities of proteinogenous substances.

On the basis of pharmacological studies of the specific alkaloids only ergotoxine and ergotamine stimulate uterine contractions. Of the non-specific amines, histamine and tyramine exert a weak oxytocic effect.

Very few reports on the clinical action of ergotoxine are available. Kehrer (1911) found that injections of 1 to 2 milligrams were ineffective. Sharp (1911) found its action when injected more prompt but weaker than whole ergot preparations. Mor (1932) discovered ergotoxine to be very active when given parenterally but practically inactive by mouth. Using muscle strips from the human uterus, Robson (1933) found ergotoxine to be very active *in vitro*.

Jaeger (1913), Bourne and Burn (1927) and others found that hypodermic administrations of histamine stimulated the uterus during labor but noted unpleasant side effects such as headaches, flushing and nausea. Kehrer (1911) on the other hand, was unable to confirm the findings of uterine stimulation. Using tyramine, Heimann (1912) concluded that this drug produced a desirable oxytocic effect (without the toxic effects of histamine).

Since the isolation of ergotamine in 1918 numerous favorable clinical reports have appeared with both intramuscular and oral administration of this drug. Hellman (1927) recommends ergotamine for postpartum hem-

orrhage, incomplete abortion, menorrhagia, and metrorrhagia. According to this author hypodermic and oral administration are of equal value. Turolt (1923) makes the same recommendations and uses ergotamine successfully in the completion of incomplete abortion. Bourne and Burn (1927) state that ergotamine produced a powerful contraction of the uterus for 16 hours during the first stage of labor when 1 milligram was injected intramuscularly. Suchs (1932) found that gynergen (ergotamine tartrate) when given by mouth increased the rate of involution of the puerperal uterus. Moir (1932) discovered that ergotamine when given by mouth, exerted a very weak effect, and was quite active when injected intravenously or intramuscularly. On the other hand, Adair and Davis (1934) also recording contractions by means of a balloon in the uterine cavity connected to a recording manometer were unable to show any effect on the contractions or muscle tone of the uterus by injection of 1 cubic centimeter of gynergen intramuscularly.

One can readily understand that from these divergent results of clinical investigation it is difficult to draw very definite conclusions. Nevertheless on the basis of the pharmacological and clinical data, both ergotamine and ergotoxine have become generally recognized as the active or specific principles mainly responsible for the major oxytocic effect of ergot. As a result, an attempt has been made to standardize ergot with respect

TABLE I.—RESULTS

Table I is a tabulation of 30 experiments all done on the sixth day of the puerperium.
The uteri were inactive and practically in the same physiological state.

Drug	Dose	Mode of administration	Time of onset	Derivative of latency	Remarks
Fluid extract ergot U S P	cm (1 mgm.)	Oral	5 5 sec.	None	Intermittent strong contractions
Fluid extract ergot U S P	c.cm (1 mgm.)	Oral	8 sec.	Slight, 1 min.	Intermittent strong contractions
Fluid extract ergot U S P	3 cm (3 mgm.)	Oral	0 min.	hr 3 min.	Tetanic followed by strong contractions
Fluid extract ergot U S P	4 cm (4 mgm.)	Oral	6 min.	hr 30 min.	Tetanic followed by strong contractions
Fluid extract ergot U S P	4 c.cm (4 mgm.)	Oral	14 min.	hr 33 min.	Tetanic followed by strong contractions
Fluid extract ergot U S P	8 c.cm (8 mgm.)	Oral	7 min.	hrs plus	Tetanic followed by strong contractions
Aqueous ergot (ergotole)	c.cm (0.5 mgm.)	Oral	7 sec.	None	Strong contractions every 1 to 3 minutes
Aqueous ergot (ergotole)	cm (0.5 mgm.)	Oral	min.	Transitory	Strong contractions every 1 to 3 minutes
Aqueous ergot (ergotole)	4 c.cm (4.0 mgm.)	Oral	14 min.	hr 6 min.	Tetanic followed by strong contractions
Aqueous ergot (ergotole)	4 c.cm (4.0 mgm.)	Oral	9 min.	hr plus	Tetanic
Aqueous ergot (ergotole)	4 c.cm (0 mgm.)	Oral	7 min.	hr 40 min.	Tetanic followed by strong contractions
Aqueous ergot (ergotole)	cm (0.5 mgm.)	Oral	6 min.	10 min plus	Tetanic
Aqueous ergot (ergotole)	3 c.cm (7.5 mgm.)	Oral	0 min.	hr 10 min.	Tetanic followed by strong contractions
Aqueous ergot (ergotole)	0 c.cm (0 mgm.)	Oral	3 min.	Over hrs	Strong tetanic
Aqueous ergot (ergotole)	8 cm (8 mgm.)	Oral	7 min.	hr 30 min.	Strong tetanic
Aqueous ergot (ergotole)	10 m (1 mgm.)	Subcutaneous	min.	30 min.	Gradual onset of contractions
Aqueous ergot (ergotole)	10 m (1 mgm.)	Intramuscular	min.	40 min.	Gradual onset of contractions
Ergotamine ethane sulphonate	mgm.	Oral	36 sec.	None	Occasional weak contractions
Ergotamine ethane sulphonate	mgm.	Oral	33 sec.	Transitory	Weak contractions every 3 min.
Ergotamine ethane sulphonate	3 mgm.	Oral	34 min.	Transitory	Strong intermittent contractions 1 to 3 min.
Ergotamine ethane sulphonate	mgm.	Intramuscular	33 sec.	Transitory	Weak intermittent contractions
Ergotamine ethane sulphonate	mgm.	Intramuscular	3 sec.	hr	Strong contractions followed by tetanic
Ergotamine ethane sulphonate	3 mgm.	Intramuscular	14 min.	30 min.	Gradual onset of contractions
Ergotamine ethane sulphonate	30 m.	Intravenous	min.	30 min.	Gradual onset of contractions
Ergotamine tartrate (gynergen)	mgm.	Oral	33 sec.	None	Weak contractions every 3 to 5 min.
Ergotamine tartrate (gynergen)	mgm.	Oral	43 sec.	None	No contractions in hr. 2 min.
Ergotamine tartrate (gynergen)	0 mgm.	Oral	43 sec.	None	Strong irregular contractions disappearing in hr.
Ergotamine tartrate (gynergen)	mgm.	Intramuscular	sec.	3 min.	Gradual onset
Ergotamine tartrate (gynergen)	mgm.	Intramuscular	min.	45 min.	Gradual onset. Strong contractions followed by tetanic
Ergotamine tartrate (gynergen)	20 m (0 mgm.)	Intravenous	8 min.	30 min.	Gradual onset
Scamillon (ergone)	4 c.cm.	Oral	30 min.	None	Irregular weak contractions
Scamillon (ergone)	cm	Intramuscular	18 min.	Transitory	Good contractions
Scamillon (ergone)	cm	Intramuscular	0 min.	hr 40 min.	Strong contractions
Ergonovine	cm (1 mgm.)	Oral	3 min.	None	Weak contractions
Flaccidone	mgm.	Intramuscular	10 min.	min.	Tetanic followed by weak contractions
Flaccidone	mgm.	Oral	No effect	No effect	No effect
Alkaloidal free ergot fraction	cm (0 mgm.)	Oral	No effect	No effect	No effect in hrs
Alkaloidal free ergot fraction	3 c.cm (1 mgm.)	Oral	No effect	No effect	No effect in hrs
Alkaloidal fraction	cm (1 mgm.)	Oral	8 min.	40 min.	Gradual onset of tonic contractions
Alkaloidal fraction 3 Ergotamine removed	3 cm (3 mgm.)	Oral	9 min.	37 min.	Tetanic alternating with contractions
Alkaloidal fraction 3 Ergotamine removed	6 c.cm (1000)	Oral	8 min.	33 min.	Tetanic alternating with contractions

All preparations except those prepared by Dr. M. Thompson were obtained from the Johns Hopkins Hospital pharmacy. Ergotole and fluid extract of ergot were assayed by the Broom-Clark method. Ergotole contains not over 0.5 mgm. per c. cm. of ergotamine. Fluid extract Ergot U S P contains not less than 0.5 mgm. per c. cm. of ergotamine. Equivalents given in mgm. in this table are on basis of assay by the Broom-Clark method.

Fig. 15. Fraction 3 (total alkaloids with most of the ergotamine removed), 4 cubic centimeters orally. Contractions began in 15 minutes. Strong contractions alternating with periods of tetany lasted over 3 hours, 30 minutes.

2 Oral administration of ergotamine, ergotamine, and sensibamin give slow and variable results. The onset of their action varies between 25 and 55 minutes. The contractions are weak and irregular and tonus is absent. These drugs given by mouth are of no clinical value in the puerperium.

3 Aqueous ergot preparations induce an activity far out of proportion to the amount of the hitherto identified specific alkaloids present in the solution. This fact suggests that ergot also contains an unidentified active principle.

4 Ergotamine, ergotamine, and sensibamin by intramuscular and intravenous routes are indistinguishable from each other in their oxytocic effect on the postpartum uterus. Dosage of 2 milligrams of these alkaloids by the intramuscular route in the majority of cases produces a good clinical effect but unpleasant side effects with this dosage are occasionally experienced. In doses of less than 2 milligrams the results are often variable.

5 Fluid extract of ergot U.S.P. and aqueous extract (ergotole) produce a more rapid stronger, and lasting effect by mouth than ergotamine, ergotamine, and sensibamin when given by the intramuscular route.

6 Histamine when given by mouth, is inactive, and by the intramuscular route has a rapid but slight, oxytocic effect.

7 Fractions of ergot containing no alkaloids as determined by the Thompson method of extraction when given by mouth in large doses, exert no oxytocic effect.

8 Fractions of ergot containing nothing but the total alkaloids exert an oxytocic effect similar to the U.S.P. fluid extract of ergot and to aqueous extract. This indicates that the active principle is either an alkaloid or some chemical substance closely associated with the alkaloidal fraction.

9 Alkaloidal fractions ergotamine having been removed exert an oxytocic effect identical with that produced when ergotamine is present. This indicates that ergotamine is not responsible for the major effects.

THE PRESENT STATUS OF THE STERILITY OF SURGICAL CATGUT SUTURES

WITH PARTICULAR REFERENCE TO AMERICAN MADE CATGUT

RALPH OAKLEY CLOCK, M.D. F.A.C.P. NEW YORK

AS a result of his finding (6) virulent spore forming anaerobic bacteria of the gas gangrene group in a batch of catgut sutures used in the operative wounds of 5 patients in a New York City hospital, and in whom fatal gas gangrene occurred—coupled with his recovery of the same organism from one of the fatal cases—a comprehensive study of the sterility of catgut was proposed by Dr Frank L. Meleney. His aim was that it shall not be possible for anyone to buy on the market catgut that is not absolutely sterile (4).

At the Clinical Congress of the American College of Surgeons in 1929 Meleney (4) reported the results of his preliminary study. He stated

The Hospital Standardization Committee of the American College of Surgeons promised that if the results of this study were entirely satisfactory they would recommend the products of only those firms which were willing to subject their goods to this test, not occasionally but with specimens from every single sterilized batch of material. It was felt that all of the reputable firms would be willing to follow the lead in the matter and adopt the standard test and any firms which did not fall into line would find no market for their goods. If hospitals and doctors

the country over then followed the advice of the committee they could buy catgut with perfect confidence and perfect security and the risk of fatal accidents such as I have described would be reduced to a minimum.

Later Meleney and Chatfield (5) submitted an effective test for the sterility of catgut and reported that the products of ten firms had been found sterile while the sutures of seven firms proved to be non-sterile when subjected to this test.

In view of this excellent and comprehensive bacteriological study it is most unfortunate that the Meleney and Chatfield technique was not adopted as a standard method to be enforced by some controlling authority. As so aptly stated by Meleney (4)

I believe that you will all agree with me in this, that there should never be any competition of catgut firms in the matter of sterility. Their products may vie with one another with respect to other physical characteristics—tensile strength, absorbability and what not, but they should all have the common factor of sterility. There is no relative about sterility. It is an absolute term which means the absence of living elements.

For the purpose of determining the practical value of the Meleney and Chatfield test for

TABLE I—TOTAL QUANTITY TESTED OF THE TWELVE AMERICAN BRANDS OF CATGUT SUTURES

Year	Number of lots	Number of sutures
1929	87	916
1930	101	1,064
1931	142	1,482
1932	136	1,330
1933	139	1,392
Totals	605	6,184

sterility of catgut, especially since it was proposed to establish the test as a standard it seemed highly desirable to apply this technique to a large number of lots of sutures of all of the American brands over a considerable period of time. I decided to undertake such an investigation and, beginning early in 1930 and continuing each year thereafter I purchased periodically in the open market several lots of sutures of each of the twelve American brands of catgut.

During the course of this investigation I made an intensive study of the possibility of effectively sterilizing catgut by means of chemical treatment. My research on that subject (2) showed the necessity of making chemical analyses of some of the sutures before subjecting the lot to bacteriological examination, and it also emphasized the importance of using as a preliminary step in the technique suitable neutralizing fluids to dissolve and remove any chemical with which the sutures might be impregnated. Further I devised and recommended three additional controls and further safeguards for use with the Meleney and Chatfield test.

The present investigation involved a total of 605 lots comprising 6,184 catgut sutures tested during a period of five consecutive years including 1930, 1931, 1932, 1933, and 1934 (Table I). The sutures were examined bacteriologically by the Meleney and Chatfield method, or, by their method in conjunction with the use of the special neutralizing solutions which I have previously reported (2).

Results in 1930 Tests were applied to 87 lots comprising 916 catgut sutures. Seven brands were uniformly sterile while the five brands of Manufacturers A, E, F, G and I were found to be non-sterile (see Table II)

TABLE II—PERCENTAGE OF NON STERILE LOTS OF CATGUT SUTURES OF THE TWELVE AMERICAN BRANDS

Manufacturer	1930 per cent	1931 per cent	1932 per cent	1933 per cent	1934 per cent
A	100	50	78	85	91
B	0	0	0	0	0
C	0	0	0	0	0
D	0	0	0	0	0
F	20	57	83	0	0
F	50	100	88	57	33
G	100	42	12	0	25
H	0	0	0	0	0
I	5	0	18	16	12
J	0	33	0	33	0
K	0	0	0	0	0
L	0	0	0	0	0

Results in 1931 This year, 101 lots representing 1,064 catgut sutures were tested. Again seven brands were sterile, while the five brands of Manufacturers A, E, F, G and J were non sterile. Four of these non-sterile brands (products of Manufacturers A, E, F and G) were also non sterile in 1930 (see Table II)

Results in 1932 In this year, 142 lots consisting of 1,482 catgut sutures were subjected to tests for sterility. Again, seven brands were uniformly sterile while the five brands made by Manufacturers A, E, F, G and I were non sterile. These are the same five brands which proved to be non-sterile in 1930, and from them (products of Manufacturers A, E, F and G) were also found non-sterile in 1931 (see Table II)

Results in 1933 Tests were applied this year to 136 lots comprising 1,330 sutures. Eight brands were sterile while four brands of Manufacturers A, E, F and G were found to be non sterile. Two of these non sterile brands marketed by Manufacturers A and F, were also non-sterile in 1931 and 1932. One brand the product of Manufacturer I, was found non-sterile in 1930 and 1932. The other non-sterile brand marketed by Manufacturer J, was found non-sterile in 1931 but was found sterile in 1932 (see Table II)

Results in 1934 Tests were applied to 139 lots comprising 1,392 catgut sutures. Seven brands were uniformly sterile while the five brands made by Manufacturers A, E, F, G and I were non sterile. Three of these five brands which proved

also in 1930 and 1932. Two of these non sterile brands, made by Manufacturers A and F were found non sterile also in 1931 and 1933. Two non sterile brands marketed by Manufacturers E and G were also non-sterile in 1931. The other non sterile brand marketed by Manufacturer I was non sterile also in 1933 (see Table II).

THE NEED FOR STERILITY CONTROL

This investigation which involved the bacteriological testing of several thousand of catgut sutures and which extended over a period of 5 consecutive years, has demonstrated the value of the standard bacteriological test proposed by Meleney and Chatfield. When used with the three additional controls and the special neutralizing solutions which I previously reported (2) their bacteriological test has been found to be an efficient and reliable test for the sterility of surgical catgut sutures.

The results of my investigation of the sterility of American made catgut sutures have demonstrated conclusively two important facts: first that in spite of the widespread interest manifested in Meleney's study of catgut sterility and his recommendation for its control, there are still being marketed several brands of American made catgut sutures which are non-sterile and second that the need for an adequate control of the sterility of catgut sutures manufactured and sold in America, and which was apparent in 1929, still exists.

In 1931 the American Medical Association appointed a Committee on Catgut Standards for the purpose of studying and recommending a suitable sterility standard and a method of enforcing compliance with such a standard by some established authority. A report from this Committee has not yet been published and non sterile catgut sutures continue to remain a menace to the surgical and hospital professions and to surgical patients, as indicated by the results herein described.

In Great Britain the Therapeutic Substances Regulations prescribe a bacteriological test to which specimens taken from every lot of sutures sold in that country must be submitted. However the Regulations unfor-

tunately do not provide for the use of special neutralizing solutions so that chemically sterilized sutures which are not actually sterile but in which bacterial activity has been inhibited will pass the test. This was demonstrated in my recent research work on the sterility of foreign made catgut sutures (3) wherein I showed that non sterile sutures are being manufactured and sold in England and that similar conditions exist in France, Germany, Japan and Spain. Hence there is a world wide need for the control of catgut sterility.

In this connection however it should be pointed out that Great Britain following the exhaustive survey of catgut sterility by Bulloch was quick to recognize the importance of controlling the sterility of catgut sutures as evidenced by the prompt enactment of the Therapeutic Substances Regulations of January 17, 1930. Much credit is due Great Britain for having been the first country to take such decisive and constructive action toward safeguarding the interests of the surgical and hospital professions. If and when the United States of America adopts a standard test for the sterility of catgut sutures, it should profit by the experience gained as a result of the British Regulations by making the test sufficiently comprehensive to detect chemically sterilized sutures which contain viable bacteria whose activity has been merely inhibited by the chemical treatment. This can be accomplished by incorporating the necessary neutralizing solutions (2) as part of the technique prescribed in the test.

SUMMARY AND CONCLUSIONS

1. During a period of 5 consecutive years including 1930, 1931, 1932, 1933 and 1934 a total of 605 lots comprising 6,184 sutures and embracing twelve brands of American made catgut was subjected to a rigid bacteriological study. The products of Manufacturers A and F were found to be uniformly non-sterile in each of five consecutive years. Two brands, made by Manufacturers E and G were non sterile in 3 consecutive years and then after an interval of 1 year in which they were sterile were again found non-sterile thus being non-sterile in 4 non-consecutive years.

One brand, marketed by Manufacturer I, was non-sterile in 1930, and then, after proving to be sterile in 1931, was found non sterile in 3 consecutive years, thus being non sterile in 4 non-consecutive years. The other non sterile brand, the product of Manufacturer J was non sterile in 2 non-consecutive years (see Table II)

2 Based on the results of this investigation, it seems fair to assume that all catgut manufacturers in America are not using the bacteriological test proposed by Meleney and Chatfield (5), or, if so, they are not employing the special neutralizing solutions recommended (2) as a preliminary step in the technique.

3 Apparently the publication of the results of Meleney's study of catgut sterility has had little or no effect in ridding the market of non sterile sutures, for, during each of the 5 consecutive years since his preliminary report was made, non sterile sutures have been marketed by several American catgut manufacturers.

4. The results of this extensive bacteriological examination of American made catgut sutures carried out over a period of 5 consecutive years, as herein described have proved conclusively that the danger of non sterile

sutures still exists, thus jeopardizing the reputations of the surgical and hospital professions, as well as the welfare and life of surgical patients

5 Adequate control of the sterility of surgical catgut sutures in the United States of America by some recognized authority is of vital importance. It constitutes a serious problem and one with which the surgical profession has been confronted for many years.

THE REACTION OF LIPIDS IN THE BLOOD LEUCOCYTES TO FEVER AND INFECTION

ELDON M. BOYD M.A. M.D. C.M., ROCHESTER, NEW YORK
From the Department of Obstetrics and Gynecology, the University of Rochester

SOME time ago there was begun in this laboratory a series of investigations on the fat metabolism of the white blood cells. The original purpose was merely scientific, to study variations, if any in the several lipids which might be present in the blood leucocytes under conditions in which the latter are known to change numerically or histologically. As so often happens with research in "pure science" practical applications of the information thus derived become apparent from time to time. In so far as the present investigation has progressed to date it has be-

come more and more obvious that a definite prognostic significance may be attached to lipid analyses of the white blood cells in infective or potentially infective clinical conditions. Data will be presented in the present communication indicating that such is abundantly true in cases of fever. Whether or not the information so obtained warrants the added time and labor involved in the analytical procedure remains to be seen.

The work began with a few observations on the phospholipid content of the blood leucocytes in dogs (3). The method of separating

the leucocytes from blood plasma and the erythrocytes was described in the next paper (5) and is in many respects the most difficult step of the whole procedure. Were it possible to remove a liter or more of blood from men or women and repeat this at intervals of hours or days without any ill effect on the health or physiology of the subject it would be a simple matter to obtain enough white blood cells for lipid analysis—white cells which were entirely free from the last trace of plasma or red cells. Obviously removal of such large amounts of blood is not practical. Even if it were so it is probable that large venesections would of themselves affect the subsequent lipid content of the leucocytes, since hæmorrhage is known to produce a marked lipæmia in blood plasma (1).

Since repeated venepunctures were to be necessary in order to follow changes in the leucocyte lipids, it was decided at the beginning of this series of investigations that the method to be adopted should require not more than 50 cubic centimeters of blood. Subsequent analyses have shown that the amount of blood required depends upon the leucocyte count. When the count is 10 000 to 15 000 25 cubic centimeters of blood suffice 15 000 to 25 000, 20 cubic centimeters and over 25 000 10 to 15 cubic centimeters. In cases of leucæmia with a white cell count of 100 000 to 400 000 as low as 5 cubic centimeters of blood have been used. The citrated blood is centrifuged and the white cells removed and weighed as previously described (5). No attempt is made to purify the leucocyte fraction for two reasons first, because some of the cells would be lost and the amount of blood stated yields the minimum of leucocytes necessary for analysis and second because washing the cells might dissolve some of their lipids, particularly phospholipid. The white cells thus obtained invariably have traces of plasma and red cells they usually have a slight tan or reddish color. However changes in the lipid content of this fraction of blood have been proved to be due to changes in the leucocytes themselves. This was done by analyzing the lipid content of blood plasma and the red blood cells of the same samples of blood from which the leucocytes were obtained. It was found that

a. The total lipid of the leucocyte fraction was invariably higher than that in plasma or the red cells.

b. The percentage composition of lipids in the leucocyte fraction was different from that in plasma and the red blood cells.

c. Marked increases or decreases in lipid content of the leucocyte fraction were often accompanied by minor changes in plasma and red blood cells frequently changes in the latter two were the opposite of those in the former.

d. In a few cases sufficient blood was available to give samples of pure leucocytes. The fat content of these pure cells was within 5 to 10 per cent of that of the "leucocyte fraction" as routinely used.

For these reasons changes in the lipid content of the leucocyte fraction of blood so obtained are considered to represent changes in the lipid content of the leucocytes themselves. For the same reasons it is felt that the true absolute changes in the white blood cells are even more extensive than have been found by analysis of the leucocyte fraction. Contamination of this fraction with some plasma and red blood cells will tend to depress to some extent the marked changes occurring in the white blood cells. In the few cases in which pure leucocytes were secured the white blood cells were found to contain 5 to 10 per cent more lipids than the leucocyte fraction of the same blood.

A further factor of prime importance to the present investigations was the fact that minute amounts of lipids, as low as half a milligram, may be accurately determined by the recent improved micro-methods of lipid analysis. To W. R. Bloor and his associates go the major honors in the development of these micro-methods. Their technique still requires considerable experience before reliable results are obtained. The study of leucocytic lipids was prefaced by an analysis of the various micro-methods (4). A number of oxidative procedures were tried out, modified, and brought together resulting in the production of a general procedure whereby all the known blood and tissue lipids could be simultaneously determined.

Having developed a suitable method of analysis, the next step was the presentation

a series of tests on the lipid composition of white blood cells in normal individuals (5). No obvious changes were encountered in the white cells of pregnant women (7) although the lipids of blood plasma were all elevated (6). If anything there was a decrease in the leucocytic lipids during pregnancy, particularly in the neutral fat and cholesterol esters (7). Following parturition, however, there was a marked rise in the lipid content of the white blood cells due to an increase in phospholipid, free cholesterol, and neutral fat (7). This change did not appear to bear as direct a relation to lactation as to the involutional processes and repair. In contrast to this, the fall in plasma lipids during the puerperium was directly influenced by activity of the mammary glands. The increase in neutral fat of the white cells was taken to mean a scavenger action by these cells in removing the debris fat of the involuting uterus. The increases in phospholipid and free cholesterol were interpreted as signifying increased activity of the white cells in response to the infective agents at open surfaces.

This introduced a new concept that it was possible to determine the activity of the white cells by measuring their lipid content. As previously reviewed (7, 8) Bloor and his co-workers have shown that activity in a tissue causes an increase in its phospholipid content especially. Bloor has augmented his original studies on this relation in the corpus luteum and endometrium of the sow by showing that the same relation holds in the case of muscular tissue (Bloor and Snider 2).

Following this line of thought the lipid composition of the white blood cells was followed during convalescence from surgical operations (8). It was noted that patients who exhibited a normal healthy postoperative course had a rise in the phospholipid and free cholesterol of the white blood cells. Severe postoperative infections and death were associated with falling values for phospholipid and free cholesterol and large amounts of cholesterol ester and neutral fat. The lipid variation in the former group was indicative of increased activity, in the latter group decreased activity. In conjunction with a recent survey of the lipid changes during fever and convalescence

in blood plasma and the red blood cells, a study has also been made of the variation in the lipid content of the white blood cells. The results to be described bear out the conclusion heretofore noted that the activity of the white blood cells may be determined by lipid analysis. In such a manner it will be shown below that a 'turn for the worse' in fever patients may be predicted several days before clinically apparent. Apart from this practical application, the results are presented for their value in displaying the fat metabolism of the white blood cells during fever.

It will be unnecessary to review here the relation of the present line of work to previous histological and chemical studies on the white cells.

EXPERIMENTAL

The cases to be presented were all female patients most of whom were on the gynecological divisions of the Strong Memorial Hospital. Blood for analysis of the white cells was obtained under fasting conditions, usually in the morning before breakfast. The leucocytes were separated, extracted and analyzed by methods previously described (4, 5).

The series includes a variety of severe fever conditions a number in which the patients recovered normally and several in which the disease was prolonged or death occurred. The different reaction of the white blood cells in these 2 groups will be demonstrated below.

GROUP I—NORMAL RECOVERY FROM FEVER

CASE 1. Mrs. C. B. a 38 year old woman who on September 3, 1933, induced an abortion upon her self following the missing of 2 menstrual periods. Five days later on September 8 she complained of nausea and vomiting, coldness, and lower abdominal cramps. On entering hospital she was found to have a temperature of 38.8 degrees C. with an elevated pulse rate and respiration. No growth was obtained from a blood culture but the urine was positive for *Bacillus coli*. The temperature began to spike and her general condition became serious. Examination revealed an extensive inflammatory reaction in the pelvis with abscess formation and signs of peritonitis. On September 21 and 27 she was given 2 blood transfusions of 500 cubic centimeters each but her condition became worse. Clinically the outlook was grave.

On September 28 a sample of her white blood cells was obtained and analyzed. This revealed a phospholipid and free cholesterol content much higher

than the average normal, suggesting that she had a good response to infection by her white blood cells. Hence it was decided to perform a posterior colpotomy and relieve the pressure of pus in the pelvis.

The response to operation was striking. Her fever immediately subsided and she rapidly improved. A second analysis of the white blood cells was performed on October 3, the fourth day after operation, and a third on October 14. At the latter date she was well on the road to recovery; there was no drainage from the colpotomy tube and Dakin's irrigations returned clear fluid.

The following values were found on analyzing the white blood cells. For convenience the various lipids determined will be indicated by the following symbols—total lipid, T.L. total fatty acid T.F.A. neutral fat N.F. total cholesterol, T.C. ester cholesterol, E.C. free cholesterol, F.C. phospholipid, P.

Date	T.L.	T.F.A.	N.F.	T.C.	E.C.	F.C.	P.
Sept. 28	1,403	784	30	365	18	346	1003
Oct.	1,308	960	150	500	300	201	700
Oct. 14	123	780		618	415	203	390

It may be seen that analysis of the white blood cells in this case revealed information of much value in determining the prognosis and treatment. On September 28 the patient appeared on the verge of death and clinically it was impossible to tell whether opening the pelvis would relieve her symptoms or hasten death. At that time the leucocytes were found to have activity greater than normal according to their lipid analysis. The phospholipid content was over 1,000 milligrams per cent the free cholesterol was 248 milligrams per cent contrasted to 190 for normals, neutral fat was low—40 milligrams per cent (normal around 500) and ester cholesterol was not elevated. The significant value was the high phospholipid which always indicates increased activity. Active tissue usually also contains increased amounts of free cholesterol and low values for ester cholesterol and neutral fat, and these added features also characterized the leucocytic lipids on September 28.

Hence it could be said from the lipid analysis that this patient had a good resistance to infection and that the symptoms were due to the mass of the infecting organisms present. When this was relieved by a posterior colpotomy the active leucocytes rapidly overcame the remaining organisms. The analysis

of October 2 a few days after operation indicated a further increase in the activity of the white cells as evidenced by a rise in phospholipid and free cholesterol. During convalescence on October 14 the leucocytes still contained large amounts of these 2 lipids.

CASE 2. Miss A. C. a 26 year old negro, gave a history of having had an abortion, complete about 3 weeks previous to admission to hospital, on a pregnancy of about 6 weeks duration. She developed a fever and pain in the lower abdominal region, and on examination was found to have large, tender masses in the pelvis. Her blood Wassermann was 1+ white cell count 22,300 (88 per cent polymorphonuclears) and she had a temperature of 38.5 degrees C.

On February 8, 1934, 1 week after admission, her white blood cells were analyzed and found to contain elevated values for phospholipid and free cholesterol and small amounts of ester cholesterol and neutral fat. With this evidence of increased leucocytic activity the prognosis was good. However the abscess failed to point quickly and the temperature kept rising each afternoon. On February 13 the analysis was repeated with essentially the same results. A posterior colpotomy was performed on February 17 and, as in Case 1, the patient immediately improved.

The following values represent the results of the lipid analysis.

Date	T.L.	T.F.A.	N.F.	T.C.	E.C.	F.C.	P.
Feb. 8	1765	948	30	377	17	360	1000
Feb. 13	1,464	790	44	308	20	288	890
Feb. 19	1300	510		615	108	507	1360

The results of this case are practically identical with those of Case 1. Throughout the febrile period the white blood cells contained more phospholipid and free cholesterol and less neutral fat and ester cholesterol than the average normal. Thus although the patient appeared to have a severe infection her response to operation was immediately favorable. During early convalescence there occurred a further rise in the leucocytic phospholipid and free cholesterol.

CASE 3. Mrs. A. F. a 43 year old woman, entered hospital a convalescent from scarlet fever complaining of lower abdominal pain. Examination revealed the presence of a large abscess in the cul-de-sac of the pelvis. Her temperature varied between 37.5 and 39 degrees C. with an elevated pulse and respiration rate and a marked leucocytosis, 49,300 (93 per cent polymorphonuclears). The patient appeared very sick.

A sample of the blood leucocytes was obtained on February 5, 1934, in the morning just before a drainage tube was inserted through the posterior wall of the vagina. Three days later, on February 8 a second analysis was performed as the patient's temperature had fallen somewhat although she did not appear to have improved otherwise. Her white cell count had fallen to 14,000. On February 14 the patient was much better her temperature was practically normal, there was very little drainage from the pelvis and the white count was 19,300.

The following lipid values were obtained

Date	TL	TFA	NF	TC	EC	FC	P
Feb 5	1517	870	33	75	0	150	1.30
Feb 8	1426	78	23	303	0	31	1.40
Feb 14	1415	1200	51	52	0	521	850

This case again illustrates a severe fever with leucocytes possessing greater than normal activity according to their lipid content and distribution. The patient did not make as rapid a recovery from opening the pelvic abscess as might have been expected from the lipid values. The analysis of February 8 revealed that no decrease had occurred in the phospholipid and free cholesterol fractions and the trouble was eventually found to be an imperfect drainage. When this was corrected the patient quickly recovered. The analysis of February 14 demonstrated a marked rise in phospholipid and free cholesterol.

CASE 4. Mrs. A. F., a 32 year old woman entered hospital with an infected abortion upon a pregnancy of a few weeks duration. While in hospital her temperature suddenly rose and was found due to the presence of a pelvic abscess. On the second day of fever, February 2, 1934 a posterior colpotomy was performed from which the patient made a surprisingly rapid recovery. Lipid analyses were done on the day of operation when the patient had a temperature of 38.4 degrees C. and on the fifth and seventh days of the convalescence when the temperature was down to normal with these results

Date	TL	TFA	NF	TC	EC	FC	P
Feb 2	1664	1000	376	330		133	0.64
Feb 6	2609	313	74	660	20	618	185
Feb 13	2843	1590	06	590	8	35	90

Case 4 coincides with each of the cases cited although she developed a severe febrile reaction from the presence of pus in the pelvis. Her blood leucocytes contained large amounts of phospholipid and free cholesterol. When the

pressure of pus was relieved through drainage, phospholipid the index of tissue activity, more than doubled in value. The increase in the activity stimulating lipids was immediate following establishment of drainage and the patient as a result rapidly recovered.

CASE 5. Mrs. M. N. a 20 year old woman, at term in pregnancy, was admitted to hospital in active labor. She had not attended the prenatal clinics and was found to have a markedly contracted pelvis after labor had progressed without results. On February 1, 1934 a low cesarean section was performed following which her temperature rose to 39.2 degrees C. and remained so for 2 weeks with the patient in a serious condition. She received 2 blood transfusions of 500 cubic centimeters each.

On February 8 a lipid analysis was performed with the patient's temperature at 38.5 degrees C. and the white count 26,200. The results showed values for phospholipid and free cholesterol in the lower range of normals and much less than would be expected at this stage of the puerperium from previous analyses of normal puerpere (7). A second analysis was made on February 16 and this indicated a rise in the lipids associated with activity, phospholipid, and free cholesterol. Shortly after this the fever subsided and the patient made an uninterrupted recovery. The lipid values obtained were

Date	TL	TFA	NF	TC	EC	FC	P
Feb 8	76	583	73	233	80	208	597
Feb. 16	115	826	43	212	0	211	170

This case has been presented as an example of changes in the leucocytes during puerperal sepsis. In a normal woman there occurs a marked rise in the phospholipid and free cholesterol of the white blood cells a few days after parturition (7). In Case 5 these lipids were not elevated as would be expected indicating that the white blood cells in this patient did not at first respond to the infective process by increased activity. Fortunately for the patient no organism of marked pathogenicity was present. Blood cultures were negative and the urine contained only *Bacillus coli*. In the beginning of the third week of the puerperium the leucocytes were found to have increased phospholipid and free cholesterol over their values at 1 week postpartum. This indicates that the white cells did eventually respond with increased activity and the patient recovered.

CASE 6. Mrs. E. C. a 40 year old woman developed a cystitis and pyelitis in conjunction with

severe uterine bleeding. The menorrhagia was found, after investigation, to be due to endocrine dysfunction. She had an elevated temperature of 38.8 degrees C with a rapid pulse and respiration. The fever lasted a few days but quickly subsided under the usual treatment of rest in bed and forcing fluids. Only 1 lipid analysis was performed on this patient at the height of fever.

TL	TFA	NF	TC	EC	FC	F
17	183	95	430	66	37	1.90

The results indicate an excellent response by the white blood cells to the infection of the bladder and renal pelvis. It was quite rational to predict that the patient would make a rapid recovery which she eventually did.

CASE 7. Miss G. K., a 31 year old woman treated for agranulocytic angina. This patient exhibited a pronounced tendency toward a leucopenia each time she menstruated and during these periods was especially liable to infection. A sample of blood was obtained before one of these periods to determine whether or not there was a disposition to inactivity on the part of the blood leucocytes. The following values were obtained:

TL	TFA	NF	TC	EC	FC	F
1	247	199	14	1	14	6.8

Very little can be positively stated about this analysis except that the phospholipid content was in the low range of normals. The remaining values are near the means for healthy persons. This much can be said however that the white cell count in this patient was low and was associated with no increase in the activity of the leucocytes present. Hence the total resistance to infection of this patient decreased greatly during periods of leucopenia.

CASE 8. Mrs. H. P., a 30 year old woman was admitted to hospital 8 months pregnant with evidence of failing heart action consequent upon a rheumatic heart disease. On entering the obstetrical division she complained of dyspnea, pain over the precordium and edema of the extremities. Her blood pressure was 160 systolic and 60 diastolic and the urine contained 1+ albumin and casts. The white blood cell count was 7,550.

On February 14, 1933 a Porto-caesarean section was performed under nitrous oxide and ether anesthesia. Following the operation, her temperature rose to 38 degrees C and she had some pain and distention in the abdomen. The white cell count rose to 17,550 of which 91 per cent were polymorphonuclear leucocytes. The patient's temperature

subsided in about a week, she recovered, and was discharged from the hospital 3 weeks after operation.

Samples of blood for lipid analysis were secured before operation and on February 17, 3 days after delivery in the midst of the febrile reaction.

Date	TL	TFA	NF	TC	EC	FC	F
Feb 9	643	234	17	165	6	10	37
Feb 17	74	165	140	476	140	136	401

The lipid analysis of February 9 depicted the blood leucocytes as containing small amounts of all lipids, a condition characteristic of the leucocytosis of pregnancy as described. The response to caesarean section and postoperative fever however was quite favorable. Phospholipid was increased more than 6 times while free cholesterol was doubled. When such a change occurs, it has been found that variation in neutral fat and ester cholesterol should not be considered in computing the activity of the white blood cells. The increase in phospholipid alone is sufficient to denote an increase in activity of the white blood cells. As a result of this augmented resistance to infection the patient quickly recovered from the postoperative infection.

GROUP II—FEVER FOLLOWED BY COMPLICATIONS OR DEATH

CASE 9. Mrs. E. M., a 37 year old woman, was admitted to hospital with a high fever and a history of self induced abortion. On examination she was found to have a parametritis and pelvic abscess with signs of pelvic peritonitis. Her temperature was 39.8 degrees C, pulse rate 125 and respirations 30. Clinically the patient appeared similar to Cases 1 to 4 above. Analysis of the white blood cells revealed an entirely opposite state of affairs to the cases in Group I. The most important value again was phospholipid which was very low—300 milligrams per cent. Blood for lipid analysis was obtained just before a posterior colpotomy was performed in the hope of relieving the pus collection in the pelvis.

Following this operation the patient did not improve. Her temperature went even higher, she became irrational, and in a few days she died. The lipid analysis of the blood leucocytes just before operation yielded the following results:

TL	TFA	NF	TC	EC	FC	F
580	138	40	14		1	300

The important feature of this analysis is the extremely low value for phospholipid in spite of the marked fever. As already stated, low

values for phospholipid characterize inactive and degenerating tissue. It is obvious in this case that the response of the white cells to infection was very feeble. And it may be noted that no organisms of marked pathogenicity, such as hæmolytic streptococci were found.

CASE 10. Mrs. T. P. a 34 year old woman was brought in hospital with fever and a muttering delirium. According to her husband she was about 6 weeks pregnant and had an abortion induced upon her a few days previous to entering hospital. The patient had a temperature of 40.2 degrees C, pulse rate of 150, respiratory rate of 37 and a white count of 6,400 (88 per cent polymorphonuclears). She had obvious signs of peritonitis and blood culture revealed the presence of 250 hæmolytic streptococci per cubic centimeter.

A sample of blood was obtained shortly after admission to hospital and several hours later the patient died. The following values were noted for the leucocyte lipids:

TL	TFA	NF	TC	EC	FC	P
1245	605	0	615	506	20	41

There are several features which mark these cells as being extremely inactive or degenerate. First, the level of phospholipid as in Case 9 is very low—410 milligrams per cent for a patient with a marked fever. Free cholesterol was also low—129 milligrams per cent—while the leucocytes contained large amounts of ester cholesterol—506 milligrams per cent. The high value for ester cholesterol suggests particularly degenerate cells. The response of the blood leucocytes to infection was evidently nil and the patient died.

CASE 11. Mrs. T. F. a 21 year old woman, who entered hospital complaining of swelling and pain in her legs. She gave a history of having been delivered of a full term child about 6 weeks previous. In hospital she was found to have a temperature spiking from about normal in the morning to 40.5 degrees C in the afternoon. The left leg was swollen, hot, and tender especially along the subcutaneous veins. A diagnosis of thrombophlebitis was made and the patient put on the usual treatment of rest in bed with elevation of affected leg and ice packs.

On February 2, 1934, a few days after admission blood culture revealed the presence of 90 hæmolytic streptococci per cubic centimeter of blood. The patient was transferred to the isolation ward and given repeated small blood transfusions of 250 to 300 cubic centimeters every other day. On February 7 the first sample of blood was obtained for lipid analysis. The white cell count remained low as at the beginning, varying between 6,000 and 8,000.

On February 13 a second sample of blood was secured in conjunction with a blood culture test. The latter revealed fewer organisms per cubic centimeter of blood but the patient's temperature continued to rise and fall as before—the typical 'spiking' temperature curve of blood infection.

The third lipid analysis was performed on blood obtained before transfusion on February 15. A fourth sample of blood was taken just after transfusion had been completed, the object being to see if the donor's blood had any immediate effect on the lipids in the leucocytes of the patient. The analysis for this latter blood is the second recorded on February 15 (b). On this day the patient appeared slightly better clinically.

A few days later another relapse set in and a thrombophlebitis developed in the other leg. On February 19 the fifth lipid analysis was done and on the same day the blood culture was reported negative. Shortly after the patient developed a subphrenic abscess and several abscesses in the legs. All of these were opened and drained and the patient eventually became afebrile and recovered.

This case is in many respects remarkable as being a patient with a hæmolytic streptococcus infection of the blood who eventually recovered. The lipid analyses of the white cells were extremely interesting.

Date	T.L.	TFA	NF	TC	EC	FC	P
Feb. 7	2150	1300	2060	20	120	71	827
Feb. 13	902	1350	851	127	0	254	153
Feb. 13(a)	948	590	123	123	0	190	423
Feb. 13(b)	836	45	20	11	0	213	406
Feb. 19	1773	620	0	253	0	230	500

The phospholipid content of the white blood cells in the initial stages of the infection were within normal limits and indicated a fair degree of activity on the part of the blood leucocytes in response to infection in spite of the low white cell count. A peculiar feature of these early analyses was the presence of large amounts of neutral fat. Whether or not this had any connection with the formation of thrombi in the veins is not known. The white cells separated from blood had a peculiar sticky or gummy consistency. The cells on February 15 may be seen to have lost much of their phospholipid and free cholesterol. It was shortly after this that thrombophlebitis developed in the other leg and the patient became clinically worse. Nevertheless a sample taken 1 or 2 days after this on February 19, exhibited a sharp rise in phospholipid and free cholesterol. From then on the patient passed

into a stage of abscess formation and eventually recovered.

The effect of blood transfusion is indicated in the lipid analyses performed before and after transfusion on February 15. It may be seen that healthy blood from the donor produced a slight increase in phospholipid and free cholesterol and a more marked decrease in neutral fat. These variations indicative of increased leucocytic activity confirm the clinical observation that repeated small blood transfusions are beneficial in septicæmia.

CASE 12. Mrs. A. B., a 36 year old woman, was admitted to the medical division of the Strong Memorial Hospital with a marked fever. She was known case of chronic lymphatic leukemia and on examination was found to have a lobar pneumonia. Her temperature varied around 39 degrees C. with a pulse rate of 120. Blood examination revealed 55,000 white blood cells per cubic centimeter, 93 per cent of which were lymphocytes. The non protein nitrogen of the blood was 36 milligrams per cent and her blood Wassermann was negative.

A sample of blood for lipid analysis was obtained on March 24, 1934, through the courtesy of Dr. D. J. Stephens of the medical department. The lipid composition of the white blood cells was

IL	TLA	NF	TL	FC	PC	P
		95			1	478

The analysis indicated that the patient had a very low response to infection. The white blood cells contained small amounts of phospholipid and free cholesterol. It was later learned through Dr. J. S. Lawrence of the medical department that this patient died shortly after the above lipid analysis was performed. Such an issue was eminently predictable from the lipid analysis of the white blood cells.

In each of the cases just described the one substance which exhibited the most striking the most constant and the most significant changes was phospholipid. Increased activity of the white blood cells was always accompanied by rising or high values for phospholipid. A patient with an infection and a phospholipid content of around 1,000 milligrams per cent or higher in the white blood cells may be said to have developed an active resistance to infection and an excellent chance of recovery. If the phospholipid value is below 500

milligrams per cent in spite of the stimulus of infection then the outlook is definitely grave.

The use of this method as a means of measuring the activity of the white blood cells is thus really a functional and not a static test. What we are determining is the response of the blood leucocytes to infection, operation, parturition, etc., etc., by analyzing for an increase or decrease in the phospholipid fraction. For this reason repeated analyses are of more value than single determinations, especially where we wish to follow changes in the activity of the white cells from time to time throughout a prolonged illness.

From the results of this and previous communications it has become definitely established that to estimate the functional activity of the blood leucocytes the only substance which need be determined is phospholipid. Determination of the other fatty substances as already listed will supplement the information derived from phospholipid analyses but is not necessary. Hence the test as now used routinely in this clinic consists in the determination of the phospholipid content only of the white blood cells.

Determination of the phospholipid content of the white blood cells may be performed on a sample of blood within a few hours. If the blood is obtained in the morning before breakfast the test may be completed in the early afternoon and does not require the continuous attention of the analyst. It does require some technical experience as do all micromethods for lipid analysis.

The procedure may be briefly outlined here. For more detailed information the previous papers, discussed here, may be sought. Blood is centrifuged, the plasma drawn off and the white cell layer lying on top of the red blood cells, removed with a pipette or pair of forceps. This is quickly weighed, ground up with clean sand and alcohol ether 3:1 added with shaking. The residue is filtered off and discarded. The alcohol ether extract is then evaporated to dryness and the residue extracted with petroleum ether. From the petroleum ether extract the phospholipids are precipitated with acetone and magnesium chloride. The precipitate is dissolved in moist ether and transferred to glass stoppered flasks,

the solvent evaporated off and the remaining phospholipid residue oxidized completely with chromic acid. From the amount of chromic acid thus required the amount of phospholipid present may be calculated.

SUMMARY

The results of the present investigation in conjunction with previous reports demonstrate that the white blood cells undergo marked metabolic variations as indicated by changes in their lipid content in pregnancy, lactation, postoperative convalescence, fever, and convalescence from fever. The present report contains 26 complete differential analyses of the lipids in the leucocytes under fasting conditions in 12 cases of fever. In each analysis the lipids determined were free cholesterol, ester cholesterol, total cholesterol, phospholipid, neutral fat, total fatty acids, and total lipid. Oxidative micromethods were used.

The findings were grouped according to whether or not the resistance of the patients was sufficient to overcome the infection. In patients who recovered normally from fever due to a variety of causes, the white blood cells contained large amounts of phospholipid. There was generally also an increased value for free cholesterol with low figures for ester cholesterol and neutral fat. In these convalescence was accompanied by a further rise in phospholipid.

On the other hand, patients who died as a result of their infection were noted to have low phospholipid values in the blood leucocytes during the febrile period. The same was found true in a case of thrombophlebitis when complications developed.

From this evidence and previous data it has become obvious that the activity of the white blood cells may be measured by determining their lipid content, especially the phospholipid fraction.

Data from one case suggests that a blood transfusion may increase the activity of the white blood cells.

CLINICAL SURGERY

FROM THE WILLIS C CAMPBELL CLINIC

AN OPERATION FOR REPAIR OF THE INTERNAL AND EXTERNAL LATERAL LIGAMENTS OF THE KNEE JOINT

WILLIS C CAMPBELL, M D F A C S MEMPHIS, TENNESSEE

THE ligaments of the knee joints have certain well known functions to perform and when they are mechanically impaired by complete or partial rupture or elongation more or less disability may result. Definite lateral instability from elongation or stretching of the lateral ligament, and also definite anterior posterior instability from impairment of the crucial ligaments, are consistent with an apparently normally functioning knee. However such a knee is obviously more prone to injury from trauma than one not so affected. There are many instances in which ligament impairment does cause definite symptoms and disability which may be independent or associated with injuries of the semilunar cartilages or other derangements. There are also instances in which disability persists after removal of a cartilage which is due to rupture or elongation of ligaments. The lateral ligaments may be come relaxed following either acute trauma or repeated injury as may occur after recurrent displacements of the cartilage or other internal derangements.

When the cartilages are involved well known classical symptoms will be found. When there

has been stretching or elongation of the internal lateral ligament tenderness will be present along the attachments of the ligament or at any point where rupture may have occurred and symptoms of indefinite internal derangement and a feeling of instability may be noted. The same symptoms may be present on the outer aspect when the external lateral ligament is involved.

To determine lateral stability of the knee the joint is completely extended, the leg is then grasped by one hand just above the ankle while the other hand fixes the thigh. No motion will be present in a normal knee if the internal lateral ligament is impaired, however excessive abduction will be possible if the external, excessive adduction. Certain apparently normal individuals have hypermobile joints, in which case there may be more or less lateral motion present—an abnormality which can always be determined by comparison with the opposite knee.

The internal ligament is much more frequently involved than the external in fact I have never seen a rupture of the external ligament requiring surgery.

The same procedure can be used to repair either or both sides, when indicated, but as the internal ligament is the more frequently involved we shall describe the treatment as applied to impairment of that ligament. The technique is as follows:

A skin incision is made parallel with the quadriceps tendon the patella and patellar tendon from 2 or 3 inches above the patella to just below the tibial tubercle. The deep fascia is incised and the capsule exposed. A curved incision parallel with the patella and the upper surface of the tibia is made into the knee joint if internal impairment is suspected and such attention given as may be required, after which the joint is closed. The repair of the ligament is accomplished by dissecting from the inner aspect a strip of fascia lata about 0.5 inch in width and 4 inches in

Fig. 1 Internal incision parallel to patellar tendon, which gives access to joint and also to internal lateral ligament.

Fig. 2. Dissection of flap which is placed through tunnel down to the joint beneath the soft structures

Fig. 3. Flap drawn very taut through tunnel and stitched in place, thus tightening the relaxed ligament.

length from above down to a point about opposite the center of the inner aspect of the internal condyle of the femur. Two parallel incisions about 1 inch in length and about 0.5 inch apart are next made through the deep fascia and periosteum, about 1 inch below the upper extremity of the tibia and parallel with the joint line. An artery forceps is then passed through the lower incision close to the knee, emerging through the upper incision. The upper end of the fascial flap is grasped by the forceps and brought through the tunnel in the dense fascia and periosteum. After this the ligament is drawn tight and stitched as

high as possible to the margin of the fascia lata from which it has been dissected. The limb is held extended and forcibly adducted during the operation. By passing the fascia through the tunnel a very accurate pulley action can be made, which permits effective tightening or tautness of the capsule.

This operation has been used when there has been undue laxity of the ligament associated with injury of the cartilage, and also when there has been no cartilage impairment. The procedure has been employed for the past 2 years, and so far the results have been excellent in 3 cases.

THE SURGICAL TREATMENT OF TUBERCULOUS EMPYEMA¹

R. H. MACDONALD M.D. F.R.C.S. (C) F.A.C.S. SASKATOON SASKATCHEWAN

By "tuberculous empyema" is understood a collection of pus in the pleural sac, wherein the primary causative agent is the tubercle bacillus. Frequently however various other pyogenic organisms become associated and a resulting secondary infection is superimposed.

CLASSIFICATION

From the standpoint of surgical treatment two main groups may be recognized: (1) tuberculous empyema, (2) tuberculous empyema with secondary infection.

Hedblom and other writers divide the tuberculous form into two types: (1) primary without clinical evidence of associated pulmonary tuberculosis, (2) secondary where there is a clinically recognizable active pulmonary lesion.

The decision to apply surgical treatment is determined in the main by the condition of the underlying lung. In a classification based as primary or secondary, it is difficult to assess with accuracy the amount of lung involvement. The presence of a large pleural effusion, whether seropurulent or purulent, makes X-ray diagnosis of the pulmonary lesion often impossible. Tuberculosis limited to the pleura is generally accepted as being of rare occurrence and one must also remember that an extension of a tuberculous lesion in the lung may occur subsequent to the development of the empyema.

Archibald recognizes a seropurulent and purulent form of the tuberculous type. While the degree of infection is of much importance in that the purulent is invariably a further stage of the seropurulent form denoting also in some cases a more serious infection, the indications for surgical interference remain unaltered.

In the group of tuberculous empyemata with secondary infection, there are present added indications for surgical treatment which do not pertain to the tuberculous group *per se*. These indications may be such as have caused the mixed infection, e. g. bronchial fistula or external drainage, fixation of the cavity due to a greatly thickened pleura or long standing toxemia.

DIFFERENTIATION

It is all important that a tuberculous empyema be differentiated from one of purely pyogenic origin. Seropurulent or purulent fluid aspirated from the chest and found to contain no pyogenic

organisms should be considered tuberculous. The writer has had the experience of one case where the fluid was repeatedly sterile in aerobic culture but anaerobically gave a pure culture of *Brucella abortus*. This case, to his knowledge is the only instance of an empyema resulting from such infection and while not of frequent occurrence with the increasing incidence of undulant fever this possibility must be borne in mind. The diagnosis rests in the examination of the aspirated fluid for tubercle bacilli, guinea-pig inoculation or microscopic examination of the excised pleura in patients operated upon. Repeated examination of the fluid as well as animal inoculation may fail to demonstrate tubercle bacilli. One must then rely on other criteria to establish a diagnosis. If there is sufficient evidence to show that an insidiously developing primary pleural effusion preceded the empyema, it should be regarded as tuberculous. This fact is now generally accepted. The finding of tubercle bacilli in the sputum is presumptive evidence that an accompanying empyema is tuberculous. Empyema developing from serous effusions, the result of pneumothorax treatment, or in the presence of active pulmonary tuberculosis, may also be considered tuberculous. Too much care cannot be taken to establish a proper diagnosis as the entire future treatment depends on so doing.

Several of our cases were admitted after a rib resection with a history somewhat as follows:

"Patient is taken ill with infection in the chest and a diagnosis of pneumonia is made. After a considerable length of time signs of effusion appear. Aspiration is performed and a thin, cloudy fluid withdrawn. The temperature remains elevated, the patient is quite ill and the fluid re-accumulates. Aspirations are repeated each time perhaps the fluid is found to be slightly more purulent. No culture is made. The case is considered one of empyema following pneumonia, probably of the influenza type and a rib resection is performed.

The condition however may be an acute tuberculous infection, with effusion. The rib resection precludes the possibility of a cure by other than prolonged treatment and surgical measures. Whatever chance the patient may have had of overcoming his infection with an expanded lung is denied by the unjustifiable and ill considered external drainage. Alexander says, the keynote of treatment is that open drainage must never be instituted, and Keller states that over 50 per cent of tuberculous empyema at the Walter Reid

¹Read at the annual meeting of the Saskatchewan Medical Association, Regina, Sask. August 26, 1933.

Hospital had had previous open drainage the greatest tragedy that could befall them.

It is recognized that tuberculous patients do not tolerate an open pneumothorax. More particularly is this true in the early stages. In any case with pus in the pleural sac, surgery should not be considered until a thorough bacteriological examination of the aspirated fluid has been completed. Rarely, if ever does a chest full of pus constitute a surgical emergency. Embarrassing pressure symptoms or toxæmia can be adequately relieved by aspiration. Microscopic study and culture will readily demonstrate the presence of pyogenic organisms and no case should be subjected to drainage where bacteriological examinations have been negative.

TREATMENT

Marked absence of agreement seems to prevail as to which cases should be treated conservatively and which should be referred to the surgeon for some form of collapse.

In Saskatchewan sanatoria prior to 1925 all patients were treated by aspiration with or without air replacement by injection of antiseptics, and when secondarily infected by open drainage. Hamilton, of the Saskatchewan Anti Tuberculosis League reviewed all cases definitely proved as tuberculous over a period of years and found that in the severe mixed infection type with bronchial fistula 13 in all, 10 died, 9 of the empyema, 1 of progressive pulmonary disease. Where rib resection had been done either before or after

admission, 13 in all, 1 was well after 5 years of treatment. The remaining 12 died.

The present report includes 6 cases of the severe mixed infection type in which bronchial fistulae were present at time of operation and which were treated by thoracoplasty. These were discharged from hospital with bronchial fistula closed and cavity obliterated. There were 8 with external drainage on admission all were treated by thoracoplasty. Two patients on discharge had small sinuses in the remainder complete obliteration of the cavity was obtained.

In tuberculous empyema complete re-expansion of the lung may not be possible because of thickened pleura or parenchymal fibrosis; moreover it may not be desirable on account of the danger of lighting up disease within the lung. Consequently, obliteration of the cavity can be obtained only by some form of surgical collapse, mobilizing the rigid chest wall so that symphyseal of pleura becomes possible.

In considering the form of collapse the procedure is determined by the size and extent of the cavity. Decortication of the lung must not be considered because of underlying tuberculous disease. Hedblom reported 4 cases in 1922 in which he had performed decortication, the diagnosis being made subsequent to the operation by microscopic examination of the excised pleura. In 3 cases partial obliteration of the cavity resulted 1 patient died of hæmorrhage.

The disability resulting from surgical collapse varies with the extent of the operative procedure.

Fig 4

Fig 4 Case 1 M U Shows empyema cavity right side 3 1/4 years after onset. Intervening treatment of aspiration and irrigation subsequent to cessation of treatment developed empyema decussatus with anterior erosion.

Fig 6

months after complete posterior thoracoplasty. Cavity filled with hyaloid.

Fig 6 Case 3 M U Condition on discharge. Cavity completely obliterated following unroofing operation on residual cavity.

It is considerable where the cavity is large necessitating a complete thoracoplasty. Vital capacity is lowered. There is the usual operative risk and a certain amount of mutilation and deformity commonly result. The risk is not great provided graded operations are employed and provided the general condition of the patient is moderately good.

In addition to the usual pre-operative preparation, the routine treatment at the Saskatoon Sanatorium where the cases under review were operated on, is especially directed to minimizing as much as possible pulmonary complications, the result of upper respiratory infections. Some time prior to operation all loose teeth are extracted and carious teeth treated or filled. Special attention is paid to pyorrhea and gingivitis. The day preceding operation, a thorough antiseptic toilet of mouth, nose and throat is carried out by careful cleansing of the teeth, nasal douches, and throat gargles. This is repeated twice on the morning of operation. The same morning the patient is encouraged to empty the lungs of all sputum, first upon awaking and again when the hypodermic is given. In operative chest cases the basal metabolic rate is ascertained and vital capacity estimated. Blood urea is determined, as is also coagulation and bleeding time, and kidney function is appraised by the Mosenthal test. The anesthetic employed has been novocain 3/4 per cent combined with nitrous oxide gas and oxygen.

a Tuberculous empyema. Where there is little or no evidence of lung involvement and the fluid is seropurulent in character the treatment is the same as for a purely serous effusion. Aspiration should be resorted to only when pressure symptoms have developed or when the fluid fails to be absorbed after a reasonable period of time. When it is definitely purulent and present in large quantity, early and repeated aspiration seems to give the best results. Hamilton, of the Saskatchewan Anti-Tuberculous League, reports favorable results from aspiration and irrigation with replacement of air but that treatment should be early and frequent to prevent serious complications such as bronchial fistula or sinus in the chest wall. If however there is much underlying lung involvement, increased pleural thickening, lack of improvement in the patient's condition, or if after repeated aspirations the cavity remains undiminished, thoracoplasty should be considered.

b Tuberculous empyema with mixed infection. The mildly infected cases, without bronchial fistula or open drainage should be treated the same as the sterile group. If the toxemia is marked, drainage must be resorted to. If open drainage has been performed, further surgical procedure must be considered just as soon as the patient's condition warrants. If the infection is of long standing further reduction in the size of the cavity cannot be expected. Six cases in this

series were admitted with open drainage and in none was any appreciable diminution in the size of the cavity obtained by irrigation. Occasionally, however, after open drainage and irrigation the secondary infection is overcome and the sinus closes, with resulting clear sterile effusion. This occurred in one of our cases. If bronchial fistula develops, open drainage is indicated to be followed later by surgical collapse. In 1 case with a long standing bronchial fistula, an attempt was made to obliterate the cavity by thoracoplasty postural drainage and aspiration before and after operation being depended upon to keep the cavity evacuated. Total thoracoplasty in four stages preceded by phrenic avulsion was performed. A residual cavity of some considerable size persisted, requiring drainage, unroofing and muscle transplantation before a final closure was obtained. In such cases open drainage should be instituted prior to or during the first stage of thoracoplasty, through a small dependent opening well away from the operative field. In the acute stage after drainage Archibald counsels waiting until the patient shows evidence of overcoming the infection before undertaking further surgical procedure.

The following is a case report of a severe mixed infection, complicating an acute tuberculous effusion

CASE 1. A. M. an English male farmer aged 24 years, in March, 1930, developed pain in right chest and non-productive cough. He felt feverish but continued to work. Dyspnoea developed and he was forced to go to bed 3 weeks

after onset with a temperature of 103 degrees. The chest was aspirated and 3,000 cubic centimeters of cloudy fluid was withdrawn. No bacteriological examination of fluid was made. He was admitted to the hospital and rib resection was carried out on April 1, 1930. He had lost 15 pounds in weight, night sweats were present and a small amount of sputum. His condition following rib resection grew worse and he was transferred to the Saskatoon Sanatorium on April 17, 1930, with a temperature of 103.5 degrees, pulse 140, respirations 24-28. On April 19, a further rib resection was performed to permit of more dependant drainage. Daily irrigations with Dakin's solution were carried out and for several weeks there was no improvement. During this period the temperature varied, 103 to 105, pulse 130 to 160, respirations 24 to 48. Guinea-pig inoculation of the chest fluid was positive for tubercle

bacilli. From July 1, November there was slow but definite improvement but at no time during this period was operative interference considered justifiable. On November 20, phrenic ulsion was performed and on November 20, extrapleural collapse was begun. A total thoracoplasty in four stages was carried out between November 30, 1930 and January 6, 1931. The serious condition of this patient accentuated long intervals between stages and it is interesting to note that quite definite improvement followed each stage. The contralateral lung remained healthy. The patient continued to improve and was discharged August 1931 with small areas of 20 cubic centimeters capacity in the region of the drainage wound and without cough or sputum. This man was well and doing light work from the time of discharge 1, November 31, 1931, when he died following an operation for acute intestinal obstruction in his home hospital. (He had had a fecal fistula which necessitated operative closure following an operation for acute appendicitis in June, 1920, 9 months prior to developing tuberculosis.)

An unroofing operation should not be performed if the cavity is large. Matson reserves this operation for cavities of 150 cubic centimeters or less. Considerable shock accompanies an extensive unroofing operation and the subsequent chest wall protection is poor. This mistake was made in some of our earlier cases.

The severe mixed infection type of tuberculous empyema always presents a grave prognosis. Provided the patient's condition warrants operative interference, there should be no delay in instituting surgical measures. Archibald reports 15 cases of this type, in which 8 could be treated only by a small rib resection and drainage. These went on to death from progressive tuberculosis, at various intervals, independently of the operation. The 7 remaining were treated by total

thoracoplasty; 2 patients dying in hospital, the 5 remaining were discharged as clinically cured.

RESULTS

This paper is based on a study of 15 cases definitely proved tuberculous, referred for surgical treatment by the medical staff of the Saskatchewan Anti-Tuberculosis League during the years 1926 to 1932 inclusive. All cases in this group were of the mixed infection type. There was 1 death, a mortality by case of 6.6 per cent. A total of 44 operations were performed, the mortality by operation being 2.2 per cent.

The oldest patient was 58 and the youngest 4, the average age being 31 years. There were 13 males and 2 females. The right side was involved 8 times and the left 7. Six cases were complicated by bronchial fistula and 6 were admitted with previous rib resection; 2 had empyema necessitatis. Three showed contralateral lung disease. Amyloid disease was present to a marked degree in one case and moderately so in one other. The average length of time of the duration of the empyema prior to operation was in 14 cases 3 years and 3 months. The remaining case was a man of 58 who on admission had an empyema evidently of long standing. The history pointed to a bronchial fistula which closed from time to time.

This man was a farmer, lived in the open and for years had never consulted a doctor. The only suggestive history of tuberculosis was that 13 years previously at the age of 35 he was confined to bed with what he termed "a cold" for a period of 2 months, with cough and expectoration. Just how long his empyema had existed could not be determined. The patient died, the result of pneumonia in

the contralateral lung, 17 days after a first stage thoracoplasty. Autopsy showed chronic bilateral pulmonary tuberculosis. This was one of our earlier cases and with present experience would not now be accepted for operation.

years, 1 over 2 years and 3 between 1 and 2 years, and the remaining case less than 1 year. Two had small sinuses at time of discharge, one of these has since closed. In all others the cavity was

Three of the 15 cases were classed as mildly or moderately secondarily infected, having small loculated empyemata. One was a boy, aged 4 years, with a bronchial fistula and in which guinea pig inoculation was positive. His cavity was obliterated following drainage. This instance is unusual on account of the youth of the patient. The 11 remaining cases were classed as of the severe mixed infection type. In 6 an undocking operation was performed, in 1 case in one stage and in the remaining 5 in two stages. In these latter the cavities were large and in the light of subsequent experience extrapleural thoracoplasty would have been a better procedure. Of the 5 remaining cases, 1 was treated by posterior thoracoplasty with undocking of a residual cavity. In the 4 other cases, a total thoracoplasty was performed. Phrenic avulsion preceded thoracoplasty in 4 of the 11 cases. The cause of the mixed infection was rib resection in 6 cases, bronchial fistula in 6 cases, empyema necessitatis 2 cases, undetermined 1 case.

Of the 14 cases discharged from hospital, 13 are now living, 1 dying 4 months after discharge, the result of an operation for acute intestinal obstruction. This death cannot be attributed to the chest condition. Three patients have been discharged over 6 years, 2 over 5 years, 3 over 3

obliterated and in no case has there been a recurrence of cavity formation.

The present condition of these patients has been classified as "unimproved," "improved," or "well and working." By "well and working" is meant that a patient is able to do a certain amount of work daily. One patient is unimproved and is now in hospital elsewhere with progressive bilateral pulmonary disease. One patient is improved and one other is too recent to classify. The 10 remaining cases are "well and working." One patient reports he is able to do a full day's work on the farm. The majority of the remainder are capable of doing 4 to 6 hours of work daily. One patient was married at the time of her discharge and is now doing her own housework. This patient showed marked amyloid disease but since discharge has put on 30 pounds in weight. The majority report a certain amount of dyspnea on exertion; they tire easily but consider themselves in good health. They have been followed closely since discharge and in most instances a yearly examination has been made by a member of the medical staff of the Saskatchewan Anti Tuberculosis League.

SUMMARY

1. Adequate study of all patients with empyema should be made before any surgical procedure is performed.

2. Sterile purulent effusions should not be drained externally.

3. Secondarily infected tuberculous empyemata usually require thoracoplasty.

The following additional case histories are illustrative of the type of empyema treated.

CASE 1. M. U. aged 21 years, a nurse in training, was admitted to Fort Qu'Appelle Sanatorium, December 6, 1926. Family and past history irrelevant. Patient was in good health until November 24, 1926. She was in bed 20 days with right pleural onset, with temperature. The diagnosis was questionable tuberculous, December 1, 1926. On admission to the sanatorium she had no cough, no expectoration. X-ray films suggested spontaneous pneumothorax, right side, with effusion (fluid to level of second rib, anteriorly). In January 1927 750 cubic centimeters of pus was aspirated; the cavity was irrigated with emul. Aspiration was repeated at approximately weekly intervals and cavity was irrigated. March, 1927 pus from chest was positive for tubercle bacilli, by guinea-pig inoculation. July 1927 sputum, 3/6 ounce. Aspiration of

cavity at weekly intervals was continued, followed by irrigation and air replacement. February 1928, she began to run septic type of temperature. May 1928, sputum, 3 ounces. June, 1928 empyema necessitatis with spontaneous discharge of 6 ounces pus from chest anteriorly was diagnosed. From June, 1928, to May 1929, she had two persistent abscesses in third space anteriorly. When referred for surgical treatment in May 1929, she showed greatly enlarged liver and spleen. She had septic type of temperature. Her weight was 105 pounds. The contralateral lung was clear. June 24, 1929, a rib resection posteriorly was done for dependent drainage of empyema cavity following which abscess in anterior chest partially closed. Pus in chest again was positive for tubercle bacilli by guinea-pig inoculation. Following rib resection, the cavity was irrigated daily. The temperature abated but there was no reduction in size of cavity. September 19, 1929, a posterior thoracoplasty lower ribs, was done. October 9, 1929, a posterior thoracoplasty upper ribs, was done. Following total posterior thoracoplasty, a long, narrow cavity persisted, hourglass in shape with sinuses anteriorly over breast and posteriorly at site of rib resection. April 23, 1930, unroofing of cavity anteriorly was done. June 17, 1930, unroofing of cavity posteriorly was done. This was followed by obliteration of cavity and patient was discharged July 24, 1930. June, 1931 her weight was 130 pounds. She had no enlargement of liver or spleen. She was well nourished and appeared in best of health. She has married and does 6 to 8 hours housework daily. September 1932, her weight was 135 pounds. She continues to be in good health, with no cough, no dyspnea, is able to play golf and tennis, and swims without difficulty.

CASE 3. J. J. aged 42 years married, laborer-cook normal weight, 40 pounds, was admitted to Saskatoon Sanatorium, September 26, 1929. In February 1929, he injured the right chest falling a distance of 20 feet. There was considerable contusion of right chest but no open wound. He ran temperature of 101 degrees. He had a cough with some sputum and considerable dyspnea. He was in bed 2 weeks in hospital. The chest was strapped and he returned to work but collapsed the first day at work and returned to the hospital where he remained until April 1, 1929, with weakness, cough, and sputum. His weight was 100 pounds. At this time he had an X-ray of chest and on April 18, 1929, the chest was aspirated and thin pus was obtained. No culture was made. No guinea-pig inoculation was made. Aspiration was repeated on April 25 and in May 1929, rib resection was done. From May until admission to Saskatoon Sanatorium on September 26, 1929, he had a persistently discharging sinus and the cavity was treated by irrigation. On admission, sputum was 6 ounces, and was positive for tubercle bacilli. There was a free discharge from the sinus. The contralateral lung was good. He was put to bed and given general treatment. The condition improved and the sinus in the chest wall closed. On June 30, 1930, aspiration of the chest showed clear fluid. Five hundred cubic centimeters was aspirated and 20 cubic centimeters of 5 per cent gonococcal was injected. On July 3, 1930, 60 cubic centimeters of gonococcal was injected. On July 2, 1930, 50 cubic centimeters of gonococcal

was injected. From July to November 1930, there was no change in condition. The cavity occupied the whole of the right chest (Fig 8). Surgical collapse was decided on. Between November 4, 1930 and January 29, 1931 a complete costectomy in four stages preceded by phrenic avulsion, was performed. The cavity was not drained prior to collapse but as the fluid was clear the cavity was emptied by aspiration before and subsequent to each stage. Complete obliteration of the cavity was obtained and patient was discharged June 15 1931 4½ months following last operation. The weight on discharge was 131 pounds. He had no cough, the sputum was practically nil and negative for tubercle bacilli.

Follow up, February, 1933 daily sputum, 1 ounce negative for tubercle bacilli. The general health was good but he was dyspnoeic on continued exertion. He could do light work and had a slight morning cough.

CASE 4. A. B. aged 31 years, laborer was admitted to Fort Qu'Appelle Sanatorium, February, 1926. The previous history revealed influenza in 1918 when he was in bed 6 weeks. Subsequently he was indifferently well tired easily. In 1923 he had pain in both chests and developed cough and expectoration. In 1925 cough and sputum became worse. He was tired and weak all the time and began to lose weight. At the end of 1925 he developed fever with aggravation of symptoms. On admission, sputum was 4 to 10 ounces, positive for tubercle bacilli. It was classified 111B. The right side showed parenchymatous tuberculosis throughout, with cavitation. The left side showed an apical lesion. In November, 1926, patient developed spontaneous pneumothorax with fluid filling the whole right side. He was treated by aspiration and air replacement. By July 1927 the fluid was too thick to be aspirated. Early in 1928 he developed a bronchial fistula and irrigations were stopped. The bronchial fistula drained freely and he would cough up 16 ounces daily. From this time until 1931 he was treated with bed rest. The lesion on the left side began to clear and by July 1931 he was considered fit for surgical collapse. The sputum was positive for tubercle bacilli. From July 14 to October 24, 1931 a complete costectomy in four stages, preceded by phrenic avulsion was performed. The cavity was not drained prior to thoracoplasty. It was

considered that the large freely draining fistula would keep the cavity evacuated. This was a mistake, as after complete thoracoplasty there was a considerable cavity remaining, with sputum 6 to 8 ounces. December 18, 1931 the residual cavity was drained. Following this, the bronchial fistula closed, but the cavity did not decrease in size. March 18 1932 the cavity was unroofed and soft tissues allowed to fall in, but no healing took place. June 28, 1932 the roof of the cavity was completely excised and the cavity left open, and packed with bipp gauze. After several months of treatment with ultraviolet light on open cavity there was no attempt at filling in by granulations and on January 18 1933 two large muscle transplants from the pectoralis major in front and latissimus dorsi behind, were placed in the cavity after débridement of the cavity bed. The muscle transplants were stitched to edges and the skin closed tightly without drainage. Primary healing resulted. Patient was discharged 8 months after last operation. The sputum was reduced to 2 ounces and was negative for tubercle bacilli.

The author wishes to acknowledge his indebtedness to Dr R. G. Ferguson, director of medical services, Saskatchewan Anti Tuberculosis League, by whom this material was made available and to Drs H. C. Boughton and W. S. Barclay of the Saskatoon Sanatorium for valuable assistance and co-operation in the treatment of these cases.

UTEROSALPINGOGRAPHY BY INTERRUPTED FRACTIONAL INJECTIONS

A MODIFIED AND IMPROVED TECHNIQUE¹

MORTIMER N. HYAMS, M.D. F.A.C.S. NEW YORK

DIAGNOSIS in gynecology is based largely on the fundamental methods of examination, in association with microscopical and histopathological studies. In some instances, however the usual procedures alone are inadequate to establish a positive diagnosis, and neither the lesion nor its exact location can be definitely recognized. With the development of improved apparatus, radiopaque media and a standardized technique roentgenography has become a valuable diagnostic aid in visualizing previously obscure pathological conditions. The technique of uterosalpingography is simple and does not necessitate hospitalization of the patient, except under unusual circumstances. However its application must be limited to properly selected cases.

Uterosalpingography was originally adapted for visualization of the lumen of the fallopian tubes in cases of sterility. With continued use its diagnostic and prognostic value has increased to an extent undreamed of by its original advocates.

The accepted procedure is to distend the uterine cavity with one or two injections totalling 8 to 10 cubic centimeters of a radiopaque contrast solution and make X ray exposures. Another film is taken after an interval of 24 hours. During the course of injection abdominal cramps are not infrequently complained of in some instances so severe as to necessitate discontinuing the injection when only partly completed. The dense shadow cast by the solid column of opaque fluid in the uterine cavity often obscures the presence of small intrusions and irregularities in the contour of the lumen of the uterus and fallopian tubes and filling defects of diagnostic import may not be delineated. The forceful injection of a relatively large amount of contrast solution may result in its entrance into the vascular system. The uterus has no submucosa on account of the intimate relationship of the mucosa to the underlying plexus of vessels, any break in the continuity of the mucous membrane may be accompanied by injury or laceration of the contiguous vessel wall through which the forcibly injected solution may pass into the circulation.

To overcome some of the objections and to eliminate possible sources of error the method

which is herewith described and which is based on the following principles, has been developed.

1 Successive injections of 2 cubic centimeters each of the contrast solution are made.

2 The field is exposed to the roentgen ray after each injection and the films are developed immediately.

3 The wet films are inspected to check the technique, so that modifications may be made as are deemed necessary to give maximum diagnostic data.

PREPARATION OF THE PATIENT

To evacuate the lower bowel a mild laxative is given on the night before examination and a soap and suds enema the next morning. The bladder is emptied by voiding or catheterization. The patient is placed on an X ray table equipped with a Bucky diaphragm she is placed in the lithotomy position which is maintained throughout the examination. The vulva and vagina are scrubbed with tincture of green soap and water followed by a pitcher douche of oxyganide of mercury 1:2000 at a temperature of 110 degrees F.

TECHNIQUE

A bivalve speculum fitted with the Hyams diagnostic light carrier is placed in the vagina and the cervix and cervical canal swabbed with a 3½ per cent solution of tincture of iodine. Depending on the position of the uterus and the direction in which the portio points, a tenaculum is placed on the anterior or posterior lip of the cervix. A sterile uterine sound is introduced into the uterine cavity to determine the length and position of the canal. A flexible tipped cannula attached to a Luer syringe is inserted into the uterine canal until the shoulder of the rubber acorn fits snugly into the external os.

With traction on the tenaculum and pressure on the cannula, a small amount of air is introduced into the uterine cavity to ascertain whether or not there is leakage around the acorn. If the cervix is extensively lacerated, precluding a complete closure with the cannula, the anterior and posterior lips may be approximated on each side with a tenaculum to reduce the size of the opening to permit complete occlusion with the cannula and

¹From the service of Dr. Walter T. Dunsenberry, Department of Gynecology, New York Post Graduate Medical School and Hospital, (Columbia University).

Fig. 1. Uterosalphingography by fractional method. First exposure of a series taken October 24, 1932, before treatment, after injection of 2 cubic centimeters of radiopaque medium. Uterus partially filled.

Fig. 2. Second exposure, same case as Figure 1, after injection of additional 2 cubic centimeters. Uterus completely filled, fluid has not yet entered fallopian tubes.

to prevent leakage into the vagina. If there is no leakage the instrument is removed and a syringe filled with 10 cubic centimeters of warmed lipiodol is attached to the cannula, and enough solution is forced through to expel the air from the instrument. As soon as the oil appears at the tip the cannula is reinserted into the uterine cavity and the fractional injections are made

The contrast medium is introduced by gradual but steady pressure in five separate injections of 2 cubic centimeters each with an interval between each injection for X ray exposure and immediate development of films. During this brief period between successive exposures the wet films are inspected for control of errors in technique or to

Fig. 3. Third exposure, same case, after third injection of 2 cubic centimeters of fluid. uterus filling, fluid is seen entering the tubes.

Fig. 5. Fifth exposure same case, after a total of 10 cubic centimeters has been injected into uterine cavity. Note filling defect of uterus. Tubes well delineated. Diagnosis: submucous fibroid.

Fig. 6. Twenty-four hour exposure of same case. Dissemination of fluid throughout pelvis.

elaborate on the procedure if necessary. To preclude leakage the instrument must be held in position during the course of the examination. The entire procedure rarely requires a half hour. The patient is requested to return after 24 hours for a final X-ray exposure. This exposure is

made with the patient in the dorsal posture without preliminary preparation and completes the series of six exposures.

Most of the instruments used for insufflation and salpingography have been constructed of rigid metal, slightly curved at the distal end, and varying in size from No. 12 to 20 French. Anatomically the cervical canal is not uniform in

Fig. 7. Same case as Figure 1. Diagnosis of submucous fibroid confirmed by diagnostic curettage on October 30, 1932. This film was taken 2 months after intra-uterine application of radium, 600 milligram hours. Irregularity of uterine cavity diminished.

Fig. 8. Same case as in Figure 1. This film was taken 1 year after the application of radium. Uterine cavity appears normal. Patient asymptomatic.

Fig 9. Congenital anomaly elongation of fallopian tubes.

Fig 10. Bicornuate uterus

size, shape or course, nor is the uterus always in its normal position. In passing a large rigid cannula through the cervical canal into the uterine cavity considerable trauma may result because of the disproportion between the size of the sound and the diameter of the cervical canal the lumen of which may be distorted by congenital abnormalities or by trauma. The same principles apply also to the internal os and corpus uteri. To overcome these difficulties I have devised a flexible tip¹ for the cannula to take the place of the rigid end.

The advantage of this method of interrupted fractional injections is the complete absence of cramp-like pains or unpleasant sensations in the lower pelvis so frequently associated with the injection of the large amount of fluid into the uterine cavity at one time. The patient is comfortable and completely relaxed, she is able to remain motionless and to co-operate, all of which helps to facilitate the making of good X-ray exposures. This method of injection permits following the progress of the solution as it fills the uterus and fallopian tubes filling defects and pathological changes are more accurately visualized and located. In view of the fact that the injections are

controlled by specific quantities of the medium, physiological distention of the uterus and fallopian tubes is less dangerous and is accompanied or followed by a minimum of reaction. The technique precludes the possibility of untoward results and gives a maximum amount of information. The possibility of such disagreeable sequelae as vascular injection with the media is excluded.

Delineation of the uterine cavity by this method often differentiates an ovarian cyst from a fibroid, and will also disclose polyps or submucous fibroids protruding into the uterine cavity which might otherwise escape notice. Bicornuate uteri and other congenital uterine or tubal anomalies are clearly outlined in a uterosalpingogram.

While congenitally elongated fallopian tubes are uncommon they do occur and may be the cause of persistent sterility. A young woman presented herself for primary sterility. Repeated transuterine insufflation tests proved the tubes to be patent and a salpingogram confirmed these findings. However the tubes were found to be tremendously elongated reaching to within 1 inch of the crest of the ilium. Since the insufflation tests proved that the tubes were open it was logical to assume that pregnancy could occur but the salpingogram indicated that while possible this was extremely improbable (Fig 9).

¹The instrument embodying this improved flexible tip feature was described in detail in the *Am J Obst and Gynec* May '53.

Although skiographic delineation of the uterus and fallopian tubes has been used in the diagnosis of early pregnancy and despite the fact that abortion has seldom followed, its use for this purpose cannot be recommended. The Aschheim-Zondek test and its modifications have proved more reliable than all others for this purpose. I must confess to having inadvertently made salpingograms during the first month of pregnancy in two cases, unaware of the presence of a gestation sac. In neither case was the pregnancy interrupted by the incidental manipulations, both patients going to term and having normal deliveries.

A hydrosalpinx manifesting no gross enlargement on palpation can be demonstrated by salpingography, and an unsuspected hematosalpinx or pyosalpinx may be revealed in the same way. Salpingography is also of value in determining the presence or absence of tubes in patients who have had a previous operation on the adnexa but who are uncertain of its nature.

At all times, the degree of pressure used to inject the radiopaque medium into the uterine cavity and tubes must be moderate. Excessive distention may result in the rupture of a tube in the presence of an unsuspected tubal disease and for this reason is particularly dangerous in cases of tubal pregnancy.

Röntgenography of the pelvic viscera must be avoided during menstruation and the 5 days before the onset of a flow. The best time is about 7 days after the bleeding has stopped. A suspicion of either uterine or ectopic pregnancy is also a contra indication. It should not be attempted in the presence of active inflammation of the external genitalia, vagina, cervix or adnexa because it might be responsible for upward extension of an infection. Indiscriminate use of the X-ray and opaque medium in gynecological diagnosis must be avoided and the contra indications must be scrupulously observed.

SUMMARY AND CONCLUSIONS

1. A new method of fractional uterosalpingography is presented.
2. It has distinct diagnostic advantages over the accepted methods.
3. It is attended by little or no pain and is without danger in properly selected cases.
4. By its use, abnormalities or pathological changes, difficult or impossible of interpretation by other methods, can be frequently demonstrated.
5. The proper instruments as well as exact and careful technique are necessary to obtain the best films.
6. Hospitalization is not necessary except in unusual cases.

TUBERCULOUS ABSCESES OF THE BRAIN SECONDARY TO TUBERCULOSIS OF THE CÆCUM

CARL W RAND M.A. M.D. F.A.C.S. LOS ANGELES, CALIFORNIA

THE central nervous system is not infrequently invaded by tuberculosis. This invasion usually occurs as tuberculous meningitis miliary tuberculosis or less frequently as single or multiple tuberculomata. Tubercle or tuberculoma formations may become confluent and involve relatively large areas of the brain, caseation and breaking down of tissue with secondary infection resulting. On the other hand, true tuberculous abscesses of the brain are very rare. Their pathology differs from that of tuberculous abscesses elsewhere in the body in that it does not involve the various stages of granulomatous change to be expected from an infecting organism of this nature. Apparently these abscesses are blood-borne infections from a chronic tuberculous process elsewhere in the body. The method of abscess formation resembles that of other cerebral abscesses caused by pyogenic infecting organisms when these are blood-borne. There is probably a primary period of localized encephalitis a secondary period of softening, and a final period of capsule formation in the development of a true abscess. The case here reported is of such a type.

CASE REPORT

Tuberculous abscess of the cerebellum and right frontal lobe complicating a tuberculoma of the cecum in a Japanese 46 years old.

M. Y. Japanese male, fish merchant, aged 46 years and single, referred by Dr. K. Tashiro of Los Angeles, on October 23, 1933 for symptoms resembling those of a tumor of the brain. He was born in Japan coming to this country at the age of 18. He is said to have had an attack of acute appendicitis in 1925 for which he was not operated upon. He was a heavy smoker and drinker. There was no history of chronic cough, chills, fever, expectoration, or loss of weight. On May 12, 1932 he was examined by Dr. Walter Wemels of Los Angeles, who obtained a history that during the previous 3½ months he had developed slight pain in the abdomen morning and evening. A month prior to Dr. Wemels' examination he had had an attack of colic which lasted 1 day; this was followed by constipation which was relieved by taking some gas powders. There had never been any nausea or vomiting.

His physical examination was entirely negative except for 3 devitalized teeth, a slightly enlarged heart and a tumor mass in the right lower quadrant. This mass was described as being about the size of a lemon, rather hard, freely movable, smooth, occupying a position 3 centimeters to the right of the umbilicus and extending from the level of the umbilicus downward for 5 centimeters. The right kidney could be felt above and was distinct from the mass. A gastro-intestinal study was negative except that

the ascending transverse and descending colon was found to be narrow and spastic. The ascending colon was interfered with by the palpable mass which moved with it upon manipulation. The cecum was filled. The bowel appeared to be pushed to the extreme right. No appendix was seen. The blood Wassermann was negative. Urinalysis and examination of the stool were negative. Blood count: hemoglobin 80 per cent, red blood cells 4,480,000, white blood cells 14,000, differential lymphocytes 26 per cent, polymorphonuclears 57 per cent, large lymphocytes 9 per cent, mononuclears 5 per cent, eosinophils 3 per cent. The diagnosis at that time seemed to rest between (a) perityphilitis, (b) Meckel's diverticulum, (c) omental cyst, (d) hydatid cyst, and (e) carcinoma of the cecum. An exploratory laparotomy was recommended but was not carried out.

When first seen by me on October 22, 1933, a different picture presented. There was a large movable tumor in the right lower quadrant of the abdomen which was not painful or tender on pressure but which was now about the size of a man's fist. The patient gave a history also of periodical attacks of partial intestinal obstruction. Roentgenological studies following a barium meal test showed a marked filling defect in the region of the cecum.

There was a further history of headaches dating back about 4 weeks. The pain was most marked in the right suboccipital region. There had been a great deal of nausea and frequent vomiting. The patient had lost weight. He had been unsteady on his feet and apparently very ataxic. He preferred to lie on the right side, becoming very dizzy if he turned to the left side. One made out no evidence of tuberculosis in the chest. The sense of smell was present on the right side but lost on the left side. His discs showed no choking. There was a slight horizontal nystagmus on looking to the right, none on looking to the left. There was slight weakness of the right lower face. The Romberg symptom and gait could not be tested but when propped up in bed the patient fell backward and to the right. There were no abnormal reflexes of the Babinski group on either side. No ankle clonus was present. Blood Wassermann was again negative. A spinal fluid examination showed a clear fluid, containing one cell, marked increase in globulin, negative Wassermann. Colloidal gold curve oooooooooo. No tubercle bacilli or other organisms were seen.

The presence of an expanding lesion in the right cerebellar lobe was suspected. The question arose as to whether this was secondary to the tumor in the abdomen and an exploratory laparotomy was suggested.

On October 28, 1933 the patient was operated upon by Dr. K. Tashiro. At operation the mass proved to be an extensive tubercular lesion involving a very movable cecum and the adjacent terminal ileum, with regional mesenteric and omental changes. The cecum and lower portion of the ascending colon were quite thickened and moderately indurated as was also a portion of the terminal ileum about 3 inches long. The appendix was retrocecal and bound down in a mass of adhesions. An extensive resection of the cecum and ascending colon as high as the hepatic flexure and also including 6 inches of the terminal ileum was carried out. An isoperistaltic side-to-side bowel anastomosis was then done, uniting the transverse colon to the terminal ileum. The wound was drained with a cigarette

Fig. 1. Cerebellum cut in horizontal plane to show tuberculous abscess in cerebellar lobe adjacent to vermis.

Fig. 2. Coronal section of brain showing tuberculous abscess in right frontal lobe. Note the discrete capsule and absence of gross inflammatory changes about the abscess.

drain and then closed. Following this, so far as abdominal symptoms were concerned, the patient made an uneventful convalescence. The wound healed *per primam* and free bowel motion was re-established.

About a week after this the patient suddenly began to develop signs of meningeal irritation, stiffness of the neck, a positive bilateral Kernig sign and drowsiness. His temperature suddenly arose to 104 degrees. His coma deepened and he died on November 6, 1933. An autopsy of the brain was permitted. Gross and macroscopical study of this organ and of the resected cecum were reported by Dr. C. B. Courville of Los Angeles in part as follows:

Gross pathology. The specimen consists of the dura mater covering the dorsolateral surfaces of the cerebral hemispheres, the entire brain and the cecum, the latter being a surgical specimen.

Brain. The convolutions of the brain over the right hemisphere seemed to be somewhat universally flattened as compared to those of the opposite side. There were no particular areas, however, in which any unusual flattening was observed to point out the location of an underlying lesion. There has been in the recent state a fairly marked cortical congestion, and many of the smaller radicals are still visible even after embalming. The arteries are rather thin-walled throughout, although their tortuosity, especially over the cerebral cortex, would suggest that the patient was past middle age. The arachnoid shows considerable minor thickening and opacity in the region of the sylvian fissure, but not to the extent indicative of an inflammatory process.

One rather interesting incidental finding is the extremely small size of the olfactory tracts, which are found as thin, string-like structures in the olfactory sulcus. There is a minor grooving of the uncinate region on either side

and extends back, particularly on the left to include a part of the hippocampal gyrus.

There is a bilateral herniation of the cerebellar tonsils about the medulla in the region of the foramen magnum. There is also a marked herniation of the anterior two-thirds of the superior vermis and an adjacent triangular portion of the superior surface of the left cerebellar hemisphere through the tentorium. This herniation is undoubtedly due to the occurrence of a cerebellar lesion to be described later, and has taken place caudal to the brain stem.

On the midpoint of the upper surface of the right cerebellar hemisphere adjacent to the vermis there is what appears to be a thicket area in this region, indicating its presence by loss of cortical markings, which measures 1.7 by 3 centimeters in its present state. The folia about this area are likewise considerably flattened and distorted.

The cerebellum was cut in a horizontal section, passing through its anterior and posterior margins. This section reveals a fairly large encapsulated abscess in the upper part of the medial position of the right cerebellar hemisphere, extending into the adjacent vermis (Fig. 2). There is apparently the capsule of this abscess observed on the superior surface of the lobe. The abscess in its collapsed state measures 2.1 by 2.7 by 3.2 centimeters in its greatest transverse diameters. There is no evidence of loculation and diverticula from the main abscess cavity. The cavity is lined with a slightly uneven but well defined layer of greenish colored granular pus.

"There is next found a somewhat indistinct connective tissue capsule which varies between one-half and one millimeter in thickness. Outside of this a third layer is found consisting of a narrow, very well defined zone of reaction which is bright red in color and is evidently accompanied by considerable local congestion. The adjacent brain tissue seems to be remarkably well preserved. There is no evidence of rupture of this abscess. There is, however, considerable distortion and flattening of the fourth ventricle, which is reduced to a mere transverse slit. The dorsal

nucleus on the right is likewise compressed and distorted. There may be a slight edema of the white substance of the right cerebellar lobe as compared with the left. The abscess seems to have occurred predominantly in the narrow strip of white matter which radiates around the vermis toward the medial end of the posterior border of the lobe and has not disturbed the main centrum to any appreciable extent.

"The cerebral hemispheres were sectioned in a coronal fashion beginning at the frontal lobes. The section which passes through the tips of the temporal lobes and just anterior to the genu of the corpus callosum reveals a slightly irregular contoured oval shaped cavity in the lower outer centrum of the right frontal lobe adjacent to the sylvian fissure. It is separated by a narrow zone of white substance 1.5 millimeters in thickness and by a very much attenuated and thinned cortex from the surface of the brain. The abscess cavity measures 2.2 by 2.5 by about 3 centimeters (anteroposterior diameter) in its greatest cross-sectional diameters (Fig. 3). The central portion of the cavity was filled with liquid, greenish yellow pus, while adjacent to the capsule there was a zone of more solid pus still of greenish color but probably containing more fibrin. This pyogenic membrane can be separated from the capsule with a little difficulty showing that organization of this portion had not occurred. The active connective tissue capsule must be very thin, for it was difficult to make out grossly, and probably in no place was it more than one-half a millimeter and often much less in thickness. Surrounding the capsule proper there is a brilliant reddish zone, evidently a zone of reaction in the surrounding tissues. This, however, is sharply circumscribed and within a millimeter or two outside this zone there is remarkably little evidence of any disturbance whatever. The white substance of this side shows only slight evidence of edema, as suggested by a slight distortion of the midline structures.

"Further sections of the brain further indicate an edema of the right frontoparietal centrum. Both lateral ventricles are dilated, probably due to the occlusion of the fourth ventricle. There is a slight distortion of the ventricular pattern with a minor deflection toward the left. This seems to be even more marked in succeeding sections where the third ventricle is found to be likewise markedly distorted and also deflected toward the left. The posterior horns are markedly dilated, and in this region the ependymal lining shows a number of small discrete petechial hemorrhages. There seems to be no evidence of active inflammation in the ventricle.

Smears from both abscess activities reveal numbers of tubercle bacilli.

Cecum. The colon specimen shows a large irregular yellowish gray mass in the region of the cecum, which has invaded the bowel and caused an irregular ulceration. In this region the wall on cut section is found to be thickened, is very firm, and presents in some areas a whitish fibrous appearance, and in others a cartilaginous structure. In the outer portions of the mass there is more of a characteristic fibrous or fibrocaceous structure. As near as can be determined from the relationship of the appendix it seems as though the entire lower portion of the cecum has been involved up to the base of the appendix. The wall of the appendix likewise seems to be thickened, firm and opaque in the upper two-thirds of its extent, and on cut section the tissue has a sort of gelatinous texture so this organ has evidently partaken of the inflammatory process. The ulceration within the cecum is very irregular and there is apparently a loss of epithelium down to the firm tumor tissue (Fig. 3).

Fig. 3. Resected tuberculous mass including portions of colon, cecum and appendix, A. The tuberculous mass is indicated by arrows.

Histopathology. The following sections were taken from the abscess in the right frontal lobe.

Section 1: hematoxylin and eosin (Fig. 4). The abscess wall was characterized by an irregular friable layer of wandering cells whose structure was not clearly made out, evidently having undergone a marked degree of degenerative change. There was next a thin wall of connective tissue also infiltrated with wandering cells. Just external to this wall the brain tissue was found to be edematous and there was a certain increase in number of the interstitial cells. The overlying cortex had undergone a minor degree of edematous change and was somewhat friable, but had undergone no gross arachnoidal change. The cells forming the exudate were examined under higher magnifications, but because of degenerative change their morphology was difficult to make out, however many of them were obviously polymorphonuclear cells. There were also many mononuclear cells and some plasma cells observed. These cells could also be found in the connective tissue walls altho the mononuclear and plasma cells predominated.

Schick R for fat. There was only a minimal amount of fat in the pyogenic layer but outside of the wall were found numerous fat laden phagocytes, more abundant in some sections than others, and inclined to be scattered thru the tissue.

Section 2: Stain for tubercle organisms Ziehl Nielsen (Fig. 5). Examination of the section under oil immersion reveals a large number of beaded or granular organisms both in the exudate and in the inner portions of the capsule of the abscess. These disappeared as the outer portion of the capsule was approached, so that none was found in the adjacent brain tissue.

Gram 11-ferri stain. This method was used to determine whether or not other organisms might be present. It showed a number of beaded or granular bacilli which seemed to be enclosed in capsules. These organisms were Gram positive and were probably tubercle bacilli. Smaller forms which were rounded, resembling diplococci were also observed, which were probably small forms of the same organisms.

Fig. 4. Section of wall of frontal lobe abscess showing inflammatory reaction and connective tissue formation of capsule. No tubercles are present. Hematoxylin and eosin method. X80.

Reticulum stain. This section shows a rather condensed capsule of rather uniform size. There is slight tendency to a fibrosis of the pyogenic layer, the processes extending from the walls of local blood vessels, which at times seem to be increased in number. There is also an evident increase in number of blood vessels in some portions of the brain, from which a beginning fibrosis is taking place.

Fig. 5. Section of abscess wall right frontal lobe showing numerous tubercle bacilli scattered through the capsule. Ziehl-Nielsen method. X900.

Section 3. Gold sublimate method. This method reveals some tendency to a proliferation of the astrocytes, but rather peculiarly at a distance from the wall of the abscess proper. These cells are predominant in a layer just beneath the cortex, while the intervening brain tissue between this zone of gliosis and the abscess wall is occupied by a cell which has undergone a degree of regressive change. This differs somewhat from the usual abscess in which an active proliferation of these cells is to be found immediately outside of the connective tissue wall.

Cajal's reduced silver method. This method reveals nothing further of importance.

Section from margin of tuberculous mass in caecum. Hematoxylin and eosin (Fig. 6). The section is taken from the margin of the mass in the caecum so that normal tissue could be found to compare with the abnormal. This is also taken with the purpose in mind of observing transitional stages of the process. Even in what appears to be normal tissue grossly at the margin of the mass are observed small tubercles of characteristic structure and containing typical giant cells. These tubercles are found predominantly in the submucosa but at times are also observed in the muscular coats as well, particularly in the superficial portions. In the muscle layer and in the subserous tissues are found collections of lymphocytes with small hemorrhages about the blood vessels. As one approaches the involved area there is a gradual replacement of the normal tissues with tuberculous tissue. The muscle coat is broken up and replaced with fibrous tissue, a reticular tissue, or with typical tubercles, which may be conglomerate. The subserous and epithelial layers are quite abruptly replaced with tuberculous tissue which at first diffusely invades the normal lymphoid tissue or replaces it with discrete tubercles. The lymphoid tissue becomes less and less conspicuous until finally there remains only small lymphocytic infiltration accompanying the pathological process. The glands seem to terminate quite abruptly for a short space, however their remains can be identified by

Fig. 6. Numerous conglomerate tubercles shown in submucous coat of caecum. This process is quite different from that shown in the brain abscess of the frontal lobe. Hematoxylin and eosin method. X36.

elongated spaces filled with red blood cells. In the margin of this tuberculous mass only an occasional gland can be made out. The characteristics of the abnormal tissue are typical fibroblasts, lymphocytes, plasma cells and giant cells forming typical tubercles or a more diffuse new formed tissue.

"*Diagnosis* Tuberculous abscess of the right frontal lobe."

It is difficult to find, in the literature, reports of proved tuberculous abscess of the brain.

MacEwen (1893) discusses the possibility of abscess of the brain as a complication of tubercular disease of the middle and inner ear. He mentions the fact that there may be extensive tubercular destruction of the osseous walls, a condition which I believe is rarely seen today. When abscess occurs in such cases it is usually superficial communicating with the middle ear often by minute passage through the granulation tissue. MacEwen states "Instead of a distinct abscess in the midst of the cerebral tissues, a superficial cerebral ulceration is occasionally found in connection with tubercle of the middle ear, the pus from this ulceration being confined by the soldering of the meninges at the periphery of the ulceration to the base of the brain and the dura respectively. Such a purulent collection might thus appear as a localized cerebral abscess, the pus being retained between the brain which formed the dome and the dura which formed the floor of the abscess cavity. In his series of 25 brain abscesses there was no case of true tuberculous abscess located in the substance of the brain.

Oppenheim (1911) mentions the fact that "in rare cases the *tubercle bacillus* has been found in the internal wall of the granular tissue lining the abscess, and in the pus itself (A. Fraenkel)." He goes on to state that he himself has found the tubercle bacillus in such an abscess during operation.

Reik (1910) reports a case of cerebral tuberculosis following otitis media in a 3½ year old colored boy, which was probably not a true tuberculous abscess in the sense we have defined it. The case, the report of which is well illustrated, shows the left temporosphenoidal lobe to be almost entirely involved in the process. The disease had extended from the middle ear, solitary tubercles being found in the dura at autopsy and large areas of tuberculous caseation being present in the temporal and parietal lobes. This caseation caused considerable destruction of both the gray and white matter, but was not surrounded by a true abscess wall.

Schorstein in the Schorstein lecture of 1909 comments upon the rarity of tuberculous cerebral

abscess secondary to tuberculosis of the lungs. He cites Gowers (1888) as stating that cerebral abscess never occurs when true tuberculous cavities are present in the lungs. However this is not necessarily true, as Rudolph Meyer (1867) mentions one case of abscess of the brain with co-existing tuberculosis of the lungs. Agan Finlay (1886) quotes a case of Dr Hadden's of tuberculous pyopneumothorax with abscesses in the frontal and occipital lobes of the brain. Like wise he mentions one case recorded by Huguenin (1878). Fraenkel's case is again mentioned, and one recorded by Wernicke and Hahn where an abscess in the left occipital lobe was drained by trephining. The patient survived for 13 days and at postmortem examination tubercles were found about the abscess cavity. Fraenkel was of the opinion that there was a definite connection between the cerebral abscess and tuberculosis of the lung. Schorstein comments upon the fact of the very great infrequency of tuberculous cerebral abscess in association with pulmonary tuberculosis, calling attention to the relative frequency of brain abscess in connection with bronchiectasis. "Cerebral signs in tuberculosis of the lungs point almost invariably to tubercular meningitis. Cerebral signs in bronchiectasis mean in nearly every instance cerebral abscess."

In discussing the etiology of brain abscesses in general, Gowers (6) again (1898) states "The last local cause (extremely rare) is a tubercular growth in the brain, which has been known to break down into a collection of pus. Other tubercular tumors and other evidence of tubercle are usually present, and indicate the origin of the abscess." The tuberculous process which he describes is the more common finding and is different from the pathology which we are discussing.

Hassin (1915) reports a case of multiple tuberculous brain abscess associated with dementia. The abscesses, however "had no capsules and were separated from the cortex by an area of seemingly normal white substance. The abscess cavities were filled with a pea green to yellow colored pus of a very offensive odor." Cultures and smears made from this pus were sterile. The diagnosis of tuberculous abscess being based upon the fact that the patient had "a chronic ulcerative and miliary tuberculosis of the lungs, combined with tuberculous osteomyelitis of sternum."

Adams (1896) under the title of "Tuberculous Abscess of the Brain" reports a case of a 10 year old colored boy who died of miliary tuberculosis. The right half of the brain contained many nodular masses which were probably miliary

tubercles or tuberculomata of various sizes. In the center of these masses was an abscess mass $2\frac{1}{2}$ by 2 by $1\frac{1}{2}$ inches which contained "yellowish turbid liquid within ragged cheesy walls. These were in the right frontal lobe. The pathologist reports that the tumors in the boy's brain showed only a few giant cells, the greater part of the mass being without any recognizable structure.

Leontine (1919) reports the case of a 17 year old man with a far advanced pulmonary tuberculosis. The sputum was positive the lungs extensively involved, a tuberculous colitis was present, and a tuberculous meningitis suspected. At autopsy a tuberculous area in the parietal bone, which had caused extensive erosion, was found. The brain presented a large caseous area of tuberculosis which was apparently not a true abscess although it was so described in the title of the article.

Evans and Smith (1931) reported a case in a 14 year old girl who had an extensive scrofula of the neck of 8 years duration. This patient had daily convulsions of increasing severity for 3 weeks and a terminal hemiplegia. The spinal fluid examination 2 months before death showed a clear colorless fluid containing 9 cells—all of which were lymphocytes—trace of albumin and globulin a negative Kahn reaction and a delayed positive reaction in testing for sugar by Benedict's method. Bacteriological examination and guinea pig examinations were negative for tubercle bacilli. Another spinal fluid examination 3 weeks before death showed increased pressure, 8 cells, positive albumin and globulin bacteriological examination was negative. Before death the child developed choking of the discs, mental torpor and incoherence in speech. Autopsy showed a large abscess in the left frontal lobe which contained thick greenish pus, the examination of which revealed abundant tubercle bacilli with typical morphology. There was no evidence of general meningitis. The pus was stained by Gram's method but no organisms other than tubercle bacilli were found. The region of the abscess was described as follows: "The outer layer of brain tissue showed practically no important changes with the exception of slight edema. Bordering upon the necrotic area, there was noted a circumferential proliferation of connective tissue cells. There was likewise noted a number of new capillaries lying among the fibroblasts. These young capillaries were congested. The central area was composed of necrotic tissue, leucocytes, and lymphocytes."

Among the cases mentioned apparently that of Evans and Smith is the only one of an undis-

puted tuberculous abscess. The gross illustration of their case is identical in appearance with ours. The process of formation is apparently the same as that of an ordinary pyogenic abscess. These authors found tubercle bacilli in large numbers in the pus, but did not try to identify them in the abscess wall. Such cases are not necessarily fatal for Naffziger, has cured one such case by drain age.

SUMMARY AND CONCLUSION

A case of multiple tuberculous abscesses of the brain is reported. This is believed to represent a rare type of tuberculous reaction in nerve tissue. The usual granulomatous or tubercle formation is not present. The abscesses apparently are formed as any other pyogenic abscess of blood-borne origin are. These tuberculous abscesses, when present, almost invariably accompany some other chronic tuberculous process in the body such as scrofula, tuberculosis of the caecum or tuberculous mastoiditis. In the case here presented typical tubercle formation was present in the caecum but was absent in the walls of the cerebral abscesses.

PARALDEHYDE AS A FACTOR IN PAINLESS LABOR

HAROLD H. ROSENFIELD M.D. AND RUBEN B. DAVIDOFF M.D., BOSTON

IN a previous article (3) there was proposed a new procedure for inducing obstetrical analgesia and amnesia a method based on the use of pentobarbital sodium (nembutal) by mouth supplemented by the rectal administration of paraldehyde in olive oil. The preliminary report concerned our experience with a trial series of 50 cases. The present communication deals with the added information and experience obtained since then in a series of 300 cases.

An analysis of the first 50 cases, 30 primiparæ and 20 multiparæ is as follows:

1. The average duration of primiparous labors, after entrance to the hospital, was 10½ hours. The average length of multiparous labors was 5 hours and 20 minutes.

2. The average duration of amnesia and analgesia during labor was 9½ hours for primiparæ and 4½ hours for multiparæ.

3. The average duration of amnesia following delivery was 8 hours for all cases. Complete amnesia throughout labor was experienced by 47 patients (94 per cent). Three patients (6 per cent) experienced partial amnesia. There were no failures.

4. Twenty-eight patients (56 per cent) showed very mild restlessness, moving slightly with pains. Eighteen patients (36 per cent) showed moderate restlessness, turning from side to side or occasionally attempting to sit up with pains. Four patients (8 per cent) showed a degree of restlessness which simulated that so commonly seen with scopolamine and barbiturates or with the straight barbiturates.

5. There was no maternal mortality and but one fetal death, a case of congenital monstrosity.

6. Forty-five babies (90 per cent) breathed or cried readily immediately following delivery and 5 (10 per cent) required mild resuscitation.

In comparison with the results furnished by the trial series, we now give an analysis of the present series of 300 cases:

1. Average duration of primiparous labor was 9 hours and 45 minutes. Average duration of multiparous labor was 5 hours and 40 minutes.

2. Average duration of amnesia and analgesia during primiparous labor was 8 hours and 40 minutes. Average duration of amnesia and analgesia during multiparous labor was 5 hours.

3. Average duration of amnesia following labor was 7 hours and 30 minutes. Complete amnesia throughout labor was experienced by 285 patients (95 per cent) partial amnesia in 11 cases (3.66 per cent). There were 4 failures (1.33 per cent).

4. As to restlessness 174 patients (58 per cent) showed a mild degree, moving slightly with each pain, 104 patients (34 per cent) showed a moderate degree turning from side to side and attempting to sit up with pains, and 22 patients (7.33 per cent) showed a marked degree of restlessness thrashing about, more or less noisy, and requiring added restraint.

5. There was no maternal mortality. There were 7 still births (2.29 per cent). Of these deaths 2 were apparently due to a tight cord about each infant's neck. One was due to prematurity and one was due to a premature separation of the placenta. One showed no possible cause for death. The 2 remaining infants were definitely macerated. Eight babies died during the first week after delivery. Of these there were 3 monstrosities, 1 congenital heart, 2 cases of congenital atelectasis, and 2 cases of erythroblastosis.

6. Of the babies born alive, 264 (88 per cent) breathed or cried readily immediately following delivery, and 34 (11.14 per cent) required mild resuscitation.

7. Method of deliveries 254 patients were delivered normally or by perineal forceps, and 28 patients were delivered by mild forceps. There were 6 breech extractions and 6 cesarean sections. A Scanzoni maneuver was performed in 3 cases and a similar number were delivered by internal podalic version.

The various methods employed today for providing obstetrical analgesia and amnesia are so well known to obstetricians that we feel even an enumeration of them to be unnecessary here. Suffice it to say that thus far no one method has been found to be applicable to all cases.

The barbiturates form the basis of most of the present day procedures. Sodium isoamylethyl barbiturate (sodium amytal) and pentobarbital sodium (nembutal) are being used, either alone or in combinations with such drugs as morphia, pentopon, scopolamine or rectal ether. The results measured in terms of amnesia, have been satisfactory with most combinations. But in terms of analgesia there are sufficient disadvantages to each combination. Failure to provide analgesia has resulted in varying degrees of restlessness on the part of the patient ranging from marked excitability to violent resistance, which, although the amnesia was good, the labor not prolonged, and the infants unaffected, has led to questioning the entire desirability of these drugs. On the other hand, where satisfactory analgesia has been obtained, this has been done in some instances, at the expense of the fetus, in that varying degrees of asphyxia ranging from slow breathing to definite respiratory depression could not be avoided.

The purpose of the procedure used in the series of cases under consideration was to conserve the beneficial effects of the barbiturates in producing satisfactory amnesia and analgesia and also to discover which drug when used in combination with the barbiturates, would eliminate both the danger of excitation to the mother and the risk of asphyxiation to the fetus. Paraldehyde has been found to satisfy these requirements.

Paraldehyde according to Cushny is a polymer of ethylaldehyde. A more powerful narcotic than alcohol, it resembles the latter in its effects, but produces only rarely any symptoms of excitement. Even in large doses, it does not affect the heart directly. An important consideration in cases of cardiac disease, and produces no such effects on the protein metabolism as accompany the prolonged administration of chloral. It is observed that the pulse is somewhat slower and the carbonic acid exhaled is less than normal but these changes are not relatively greater in degree than those that occur in the course of natural sleep and must therefore be ascribed to the lessening of muscular movements. In fact, substantial quantities of paraldehyde have been taken without fatal results or with any more serious consequences than prolonged unconsciousness.

Paraldehyde is excreted in part by the lungs and for the most part in the urine. In this connec-

tion, a recent investigation (4) on the elimination of the barbiturates is of direct interest. It has been found that—

1. Amytal is excreted in the urine of humans and dogs only in traces, if at all following the administration of its sodium salts.

2. Under the same conditions, barbital and phenobarbital are excreted as such in the urine.

3. Most probably amytal and pentobarbital are rapidly and completely destroyed in the body.

It remains to be stated that paraldehyde, when used alone during labor even in very large doses, produces neither analgesia nor amnesia, but when applied in combination with the barbiturate group particularly nembutal it leads to satisfactory amnesia and analgesia.

The procedure in the present series of 300 cases differs from that used in the preliminary series, in that the alternative use of sodium amytal has been dropped and nembutal has been used entirely because of its more prompt action and because evidence has been found in this series that nembutal, when given early will not stop labor. Our procedure at present is as follows:

As soon as labor is definitely established, following the routine preparation and enema, the patient is given $4\frac{1}{2}$ grains of nembutal by mouth. This is followed in 15 minutes by 3 grains more. Now within 15 to 30 minutes of the second administration of nembutal, the patient is turned on her left side and is given a rectal instillation of 6 drams of paraldehyde in $1\frac{1}{2}$ ounces of olive oil. This mixture must be instilled high in the rectum, past the presenting part in order to avoid expulsion during a contraction.

This is facilitated by the use of an apparatus designed and described by McCormick (2). Equally satisfactory results may be obtained by using a 3 ounce glass aseptic syringe with a plunger. A No. 22 F. rectal tube is attached to either apparatus. Care must be exercised to insert the rectal tube about 8 inches without allowing it to curl on itself. If the presenting part is engaged, the tube must be inserted above it.

The mixture is then injected quickly between pains. If the glass syringe is used, a quantity of air should be left in above the solution, sufficient to insure the emptying of the catheter but not enough to cause the air to enter the rectum, for this may lead to the explosion of the solution. Following the injection a pad should be held against the anus for at least 10 minutes.

If the patient is in hard labor, the injection is further facilitated by allowing the patient to inhale nitrous oxide and oxygen until asleep.

Within 3 to 4 minutes from the time of the injection, the odor of paraldehyde becomes perceptible on the breath of the patient and she quickly falls into a deep sleep, moving or turning from side to side during contractions and sleeping soundly in the intervals. The duration of the sleep depends upon the susceptibility of the patient and may vary from 3 to 12 hours. During the first hour after injection labor may become less active in many patients, but following this period labor is spontaneously resumed and appears to progress more rapidly than in those patients who are given no medication. In the majority of cases, with the application of the medication as described labor progresses to full dilatation, and the presenting part appears on the perineum and crowns. At this stage gas-oxygen is given and delivery is completed either spontaneously or with the aid of perineal forceps. The average patient in labor will begin to show signs of awakening in 4 to 6 hours after administration. At this time a rectal examination is made (As a general rule, rectal examinations should not be performed for at least $2\frac{1}{2}$ to 3 hours after the rectal instillation, in order to avoid the expulsion of the solution.) If now we find that the patient still has several hours of labor $1\frac{1}{2}$ to 3 grains of nembutal is given by mouth. This is accomplished by placing the capsule on the patient's tongue and then dropping a small quantity of water in her mouth by means of an ordinary glass drinking tube. As the patient swallows the water she will also swallow the capsule. If this does not succeed or if the patient vomits, remove the powder from the capsule, dissolve in water or in paraldehyde and inject into the rectum. Or, the ends of the capsule may be punctured and inserted directly into the rectum with equal effect. If this dose of nembutal fails to quiet the patient, 2 to 4 drams of paraldehyde may be repeated by rectum. This will usually be sufficient to carry a patient through a 12 hour labor. Should labor be further prolonged, small amounts of nembutal with or without paraldehyde, may be repeated as necessary.

If the rectal examination reveals that the cervix has been well taken up and four or more fingers dilated, with a low presenting part, then, instead of further medication, the patient should be carried along to completion of labor by means of gas-oxygen inhalations during contractions. It has been found that with the barbiturate group greater quantities of oxygen are required in combination with nitrous oxide than is usually the case with nitrous oxide oxygen administration. Most frequently equal parts of oxygen and nitrous oxide are required. The duration of ad-

ministration of gas-oxygen is much less than with the barbiturate-scopolamine group or with straight barbiturates. In addition patients do not resist inhalation anesthesia, a situation differing from that with other drug combinations, where patients become very restless and noisy and violently resist the application of the mask to the face.

Under this form of analgesia, most patients sleep soundly and quietly through labor and move more or less with pains. Furthermore the most restless of them are rarely noisy as is the case with the use of scopolamine or of the straight barbiturate group. After a patient has been put to sleep, she should not be questioned by the attendant in order to find out whether or not she is feeling pain. Her reactions, without questioning, are sufficient evidence. Frequently a patient may complain of pain during contractions immediately fall asleep again in the intervals, and not remember her pains at all.

The question of dosage both of paraldehyde and of nembutal is of importance. In the trial series we based the amount of paraldehyde in the rectal injection roughly upon the weight of the patient. At the outset of the series, while an endeavor was made to ascertain the optimum amount of paraldehyde, several patients were given as much as 12 drams at a single dose, with no undue effects. The dose of nembutal varied from 6 to $11\frac{1}{2}$ grains, the latter in divided doses.

In the present series, the dosage of nembutal used varied from 6 to 13 grains and that of paraldehyde from 6 to 12 drams. This dosage must be varied according to individual cases, for it has been found that while the initial dose recommended has earned a few cases successfully through 12 hour labors, in some cases it was necessary to repeat as early as 3 hours after the initial dose. There is thus a certain variation of susceptibility as one might readily expect. The time for repeating the medication must be judged entirely by the reactions of the individual patient and thus precludes the setting up of any hard and fast rules. Failure to repeat medication when indicated in a given case regardless of the time element, will give rise to unsatisfactory results, such as increased restlessness and diminished amnesia. For it stands to reason that in inverse ratio to the insufficiency of dosage, restlessness must increase and the possibility is prepared for a greater percentage of failure.

It has been stated earlier that medication is started as soon as labor is established. Our index for onset of labor is the regularity and character of the uterine contractions, regardless of the height of the presenting part or dilatation

of the cervix. Medication is frequently given with a floating presenting part and a cervix which is not taken up.

In conclusion it may be stated that the deductions and experiences drawn from the present series of cases give added force and significance to the advantages observed in connection with the trial series, namely:

1. Production of prolonged amnesia and analgesia
2. Freedom of danger to the mother or the fetus.
3. Reduction of excitation to a minimum
4. Avoidance of delay in labor
5. Simplicity of administration

Articles appear from time to time in the lay press, making the assertion that painless labor in general is deleterious and is an added factor in increasing maternal and fetal mortality. On the contrary our experience with this method and also the experience of the Boston Lying In Hospital where experimental series involving most of the methods in vogue today have been carried on demonstrate that, due to the fact that patients can be allowed to remain in labor without suffering and with diminution of shock, for longer periods than is ordinarily the case there is less occasion for instrumentation and a possibility for a greater percentage of normal births. This tends to lower morbidity and mortality.

Certainly the border line patient can be given a much longer test of labor without discomfort and

shock, and not infrequently she may progress to a normal or easy instrumental delivery from below when otherwise a cesarean section would have been done.

In discussing the dangers of anesthesia during childbirth, one must differentiate between anesthesia used during actual delivery and drugs given to produce amnesia during labor. It is conceivable that a patient may die as a result of inhalation anesthesia during delivery when no medication was given to produce amnesia during her entire labor. Such a case, classified in the mortality statistics of those who die as a result of anesthesia used in obstetrics, should by no means be ascribed against painless labor.

In a series of over 1,200 cases in which various methods for producing painless labor were used, there is ample evidence to contradict statements which imply that there is prolongation of labor or deleterious effects on mother or baby. It must be emphasized that adequate dosage and constant nursing supervision is essential for satisfactory results.

THE BILE ACID FACTOR IN GALL-BLADDER DISEASE

I^N recent years the progress of gall bladder studies has been rapid. Knowledge of the methods of formations of various kinds of stones has been put onto firm scientific basis. Cholesterol has been shown to be precipitated when the cystic duct is closed for short periods and the solvent the bile salts is absorbed. It has been ascertained that long continued cystic duct obstruction leads to the accumulation of calcium either on pre-existing stones or as *Kalkmilchgalle*. Furthermore the work of many observers has shown that blockage of the cystic duct results in the prompt onset of edema and thickening of the gall bladder with infiltration of its walls by round cells. However in order to explain the train of events leading to either stone formation or chronic gall-bladder inflammation a mechanism must be discovered to account for the temporary or permanent closure of the cystic duct. Thus far this has eluded us.

Recent demonstrations of the corrosive action of pure gastric juice suggests an inter-

esting parallel. If it is true that the gastric secretions *per se* have the power to cause extensive destruction of the mucosa which secreted them why not pay equal respect to bile? This is the strongest solution which the body elaborates. Few people realize that it contains in quantities up to 10 per cent a substance that is at least as toxic as hydrochloric acid. Bile salts have been shown to have the power to cause a fatal peritonitis, pleuritis or myositis in lesser concentrations and their exceeding toxicity for all body cells is well known.

Search for the exciting agent in gall bladder disease has proved very disappointing. Bacteria are now well known to occur in normal gall bladders in about the quantity and kind as often found in diseased ones. No mechanism of stone formation in open gall bladders is at hand. Closure of the duct by inflammatory edema is a *sine qua non* in each case. The absence of a proper flora has led some to search for a chemical cause. Both pancreatic juice and Dakin's solution are known to be capable of setting up a chemical cholecystitis of a severe type. One wonders why the bile itself which is acidified in the gall bladder to a hydrogen ion concentration below any other body fluid and whose known toxicity to tissue cells is so high has not been accused of mischief.

Attempts years ago to discover a cholesterol diathesis yielded the surprising result that starvation produced the highest bile cholesterol and that meat or general overeating did not significantly raise the bile cholesterol. The colossal experiment of post war starvation in Europe produced millions of examples of high

of the cervix. Medication is frequently given with a floating presenting part and a cervix which is not taken up.

In conclusion, it may be stated that the deductions and experiences drawn from the present series of cases give added force and significance to the advantages observed in connection with the trial series, namely:

- 1 Production of prolonged amnesia and analgesia
- 2 Freedom of danger to the mother or the fetus
- 3 Reduction of excitation to a minimum
- 4 Avoidance of delay in labor
- 5 Simplicity of administration

Articles appear from time to time in the lay press, making the assertion that painless labor in general is deleterious and is an added factor in increasing maternal and fetal mortality. On the contrary, our experience with this method and also the experience of the Boston Lying In Hospital where experimental series involving most of the methods in vogue today have been carried on demonstrate that, due to the fact that patients can be allowed to remain in labor without suffering, and with diminution of shock, for longer periods than is ordinarily the case, there is less occasion for instrumentation and a possibility for a greater percentage of normal births. THE BILE ACID FACTOR IN GALL-BLADDER DISEASE

IN recent years the progress of gall bladder studies has been rapid. Knowledge of the methods of formations of various kinds of stones has been put onto firm scientific basis. Cholesterol has been shown to be precipitated when the cystic duct is closed for short periods and the solvent, the bile salts is absorbed. It has been ascertained that long continued cystic duct obstruction leads to the accumulation of calcium either on pre-existing stones or as *Kalkmilchgalle*. Furthermore, the work of many observers has shown that blockage of the cystic duct results in the prompt onset of edema and thickening of the gall bladder with infiltration of its walls by round cells. However, in order to explain the train of events leading to either stone formation or chronic gall bladder inflammation, a mechanism must be discovered to account for the temporary or permanent closure of the cystic duct. Thus far this has eluded us.

Recent demonstrations of the corrosive action of pure gastric juice suggests an inter-

esting parallel. If it is true that the gastric secretions *per se* have the power to cause extensive destruction of the mucosa which secreted them, why not pay equal respect to bile? This is the strongest solution which the body elaborates. Few people realize that it contains in quantities up to 10 per cent, a substance that is at least as toxic as hydrochloric acid. Bile salts have been shown to have the power to cause a fatal peritonitis, pleuritis or myositis in lesser concentrations and their exceeding toxicity for all body cells is well known.

Search for the exciting agent in gall bladder disease has proved very disappointing. Bacteria are now well known to occur in normal gall bladders in about the quantity and kind as often found in diseased ones. No mechanism of stone formation in open gall bladders is at hand. Closure of the duct by inflammatory edema is a *sine qua non* in each case. The absence of a proper flora has led some to search for a chemical cause. Both pancreatic juice and Dakin's solution are known to be capable of setting up a chemical cholecystitis of a severe type. One wonders why the bile itself which is acidified in the gall bladder to a hydrogen ion concentration below any other body fluid and whose known toxicity to tissue cells is so high, has not been accused of mischief.

Attempts years ago to discover a cholesterol diathesis yielded the surprising result that starvation produced the highest bile cholesterol and that meat or general overeating did not significantly raise the bile cholesterol. The colossal experiment of post war starvation in Europe produced millions of examples of high

grade hypercholesterolemia, but no increase in gall stones. It is proverbial that gall stones result from overindulgence in rich foods especially meat, and this is known to cause an increase of bile acids in the bile. Thus a paradoxical suggestion seems justified i.e. that a high concentration of the solvent may provoke an irritation capable of closing the cystic duct and that this in turn results in the absorption of the solvent and the precipitation of cholesterol.

Experimental proof of such a hypothesis is wellnigh impossible on account of the fact that any manipulation of the gall bladder of an experimental animal causes the prompt onset of a severe cystitis. We are thus deprived of controls. However anyone who has once seen the widespread inflammation caused by inserting a sterile needle into a sterile gall bladder finds it difficult to believe that the inflammation is not a chemical one and due directly to bile itself. EDMUND ANDREWS

ACUTE PEPTIC ULCER PERFORATIONS—TO DRAIN OR NOT TO DRAIN?

IN order to evaluate this subject properly both the drainage of the peritoneal cavity and the continuous removal of stomach contents should be carefully considered.

Recently the dictum as regards peritonitis, "When in doubt drain" seems well on the way to being supplanted by the slogan "When in doubt, don't drain." It has been known for some time that drainage of acute peritonitis associated with a spreading infection is not as effective as drainage of an abscess associated with a late infection. In fact, as many experimenters have demonstrated the most that can be proved for drainage of the peritoneal cavity is that it helps localize pus in cases of spreading peritonitis. However in addition to this change of general surgical opinion as regards

peritonitis, many surgeons apparently have not given consideration to the inhibitory effects of hydrochloric acid on the growth of bacteria in evaluating the question of drainage. Of course, as is well known bacteria are found low in the intestinal tract more frequently than up higher where the influence of the hydrochloric acid inhibits their growth. In other words, the reaction of the peritoneum following these perforations is due to a chemical rather than a bacterial invasion.

In replies received from over one hundred surgeons, the following information was obtained:

About 20 per cent drain in every case. Most of these employ a drain through a remote incision. About 60 per cent drain only in the late cases, or in cases in which there is evidently definite pus formation. About 20 per cent close the abdominal wall in every case without any drainage. In other words, about 80 per cent do not use drainage as a rule.

It is our rule not to employ drainage in these cases, but perhaps our judgment has been somewhat warped by having had the experience of seeing in consultation 4 cases, which had been drained all 4 of which died with duodenal or gastric fistula. In 3 of these 4 cases the drain had been improperly placed to the site of the closure, but in the 2 other cases the drains had been placed remotely—in the flank and in the pelvis, respectively.

Much work has been done on the inhibitory effects of hydrochloric acid. Even in very minute quantities hydrochloric acid has a marked inhibitory effect on the growth of bacteria. This work has been done in the test tube with the bacteria usually found in the mouth and nose, as well as with cultures taken after introduction into the stomach and duodenum.

As a rule, very seldom are bacteria found in the normal stomach. In the stomach with an ulcer having the usual increased hydrochloric

acid content, bacteria are even less frequently found. In carcinoma with a lower or absent hydrochloric acid, bacteria are frequently found.

Cultures taken of the peritoneal cavity at the time of these acute perforations seldom show bacteria, and this in spite of the observations contained in a recent article stating that there is no such thing as an "aseptic peritoneal cavity." It might be that the proper cultural methods and media were not employed in making these examinations.

Neither bile nor pancreatic juice are well tolerated by the peritoneum but with these acute perforations the quantity of either is negligible. It seems to have been proved experimentally that the digestive action of pepsin tends toward the prevention of postoperative adhesions. This is especially true when used in a 0.4 per cent solution of hydrochloric acid.

Even inert foreign bodies injected into the peritoneal cavity stimulate first the defensive production of neutrophiles and then an increase in the number of histiocytes.

After considering all these factors, there is apparently no justification for the institution of drainage of the peritoneal cavity in these cases except possibly in the very late cases showing definite pus formation. Of course, aspiration of the peritoneal cavity should be employed in all these cases while the perforation is being closed, and we all recall numerous cases in which large quantities of gastric contents have been removed, and the abdominal wall closed tightly. A few of the abdominal incisions will break down, but such an occurrence is a minor matter in comparison with a fistula. If the abdominal wall is closed with through and through "tension sutures" of some non absorbable suture material, infection of the abdominal wall will not be such a serious catastrophe, and this method will also prevent many future ventral hernias.

For some years some surgeons have advocated the immediate performance of a gastro-enterostomy following the closure of the perforation. The objectives of this procedure were

- 1 To make the postoperative discomfort of the patient less by preventing gastric distention

- 2 To aid in the future care of the ulcer, particularly in those cases which apparently would have a pyloric obstruction from the infolding of the ulcer as well as by the scar formation

In recent years the employment of the continuous suction with a small duodenal tube placed through the nose has removed the excuse for doing a gastro-enterostomy for the relief of gastric distention. The use of this tube also removes, more effectively than any other means we have, any retained old blood or other gastric residue.

In only about 10 per cent of these cases is it necessary later to do any operative work to effect a cure. This we believe is due to the improved medical care now given by the internist, and even of more value is the fact that the patient who has had the experience of having had a perforation is far more willing to take the medical cure than is the patient with an ulcer who has not had such an education.

Resections, or any type of plastic procedures, must necessarily be done with tissue which is infiltrated, and therefore unsatisfactory for suturing. In fact with desperately ill patients, it is sometimes advisable simply to plug the perforation by suturing omentum into the opening.

It is wise for the surgeon to remember that the operation is usually a life saving attempt and that the patient should not be subjected to any unnecessary procedure.

HUON H. TROUT

EARLY AMERICAN MEDICAL SCHOOLS

THE FACULTY OF MEDICINE OF MCGILL UNIVERSITY

PAUL E. ARBUTHNOT BA., LL.D. F.R.C.P. (Cant.) MONTREAL, CANADA
American Professor of Medical Jurisprudence, McGill University

THE Medical Faculty of McGill University is the successor of a brilliant period of experimental work which established it, in the third decade of the nineteenth century as the first medical school in Canada. This was the organization of the Montreal Medical Institution, an earlier existing body of which the McGill Faculty is the direct continuance and which was founded in the year 1828 by the first medical staff of the Montreal General Hospital, Drs. William F. Johnson, John Caldwell, Andrew F. Hildner and John Stephenson, the latter British military surgeon of reputation and experience, the other three Canadian who were graduates of Edinburgh University and who had qualified for the degree in various local apprenticeship and in some cases of foreign study.

Organized as a charitable trust and entrusted with the complete management and under the management administered the same under the best possible conditions the young school was kept going at once in continuity and carried on with a full curriculum but without financial aid until the year 1839. At this time a critical juncture had arisen in the affairs of McGill College which, though founded in 1828 by the will of James McGill and incorporated in 1828 as yet existed only on paper as a nominal existing staff having been appointed in 1828, one of whom, the distinguished Dr. James Fergusson of Quebec, himself an Edinburgh graduate, did not even reside in Montreal. It was however in order to fulfill the intention of the will and to secure the bequest of the founder it had become essential for the university to initiate academic activities, although owing to large donations by the benevolence of the great financiers were seriously lacking. In this dilemma, the attention of the Royal Institution for the Advancement of Learning, a body formed by Act of Parliament in 1808 and the trust under the will, was directed to this sturdy young teaching body of established reputation active in its midst, and correspondence was accordingly initiated,

with the result that, at the first meeting of Governors of "Burnside University of McGill College" the members of the Montreal Medical Institution were formally "engrafted upon" the College as its Medical Faculty "it being understood and agreed upon between the said contracting parties, that, until the power of the Charter would be lost, one of their number only should be University professor and the others lecturers." This historic event took place on June 29, 1839 at Burnside House the residence of the founder in the presence of a distinguished gathering, William F. Johnson being appointed professor and Caldwell, Stephenson and Hildner lecturers in their respective subjects. Through this arrangement the new Faculty by its activity literally saved the property of James McGill to the educational purpose for which it was designated and thereby saved the College from protracted liquidation, if not from final defeat.

The medical school was thus the pioneer Faculty in the University and it continued to be the only one in active operation during the next 25 years of the latter's existence. It was also through its devoted secretary Dr. John Stephenson the instrument whereby the requisite authority to confer degrees was obtained. Its founders are therefore to be regarded as the founders also in the academic sense of the University as a whole. In these particulars its record is, so far as we know unique in the history of early medical schools in this continent.

In other ways also, the story of its origin reveals an honorable and heroic past, that establishes a great tradition. It was founded in a time when political dissensions were rife, under great material difficulties and at the cost of much personal labor and sacrifice by men who, as in the case of the Medical Faculty of Pennsylvania, were of high professional status and, following the methods of the parent Edinburgh school made clinical instruction at the bedside an integral part of the hospital routine and an essential feature of their curriculum. So faithfully was this principle ad-

hered to by this early teaching staff and their successors, that it remained the hall-mark of this Faculty, and, during the ensuing 50 years, the 'clinical advantages' of McGill were recognised both in England and America as among the greatest available. It was indeed this early reputation that brought it, at a later period the distinction of numbering among its graduates and on its early professionate one of the greatest clinical teachers and leaders of medical thought of his time, William Osler, who graduated from McGill in 1872, and held the appointment of pathologist to the Montreal General Hospital and the chair of the Institutes of Medicine here during the first 10 years of his academic life (1874-1884). In Osler's own view this early experience was fundamental to his later progress to the status of a great clinician, and it permeates and lives again in nearly all his later medical publications. His loyalty to his Alma Mater and his acknowledgment of the value of this early influence in shaping his later career found fitting expression after his death in 1919, in the gift under his will to his old school of his great collection of books on the history of medicine, now housed in the Osler Library of the Faculty, and in the touching bequest of his ashes, which repose there behind his portrait, surrounded by the most beloved of his books.

The following is a brief outline in detail of the sequence of these events

THE RISE OF THE MONTREAL MEDICAL INSTITUTION AND THE MEDICAL FACULTY OF MCGILL UNIVERSITY

As indicated previously this Faculty was the result of three different public movements emanating from the philanthropy and foresight of the English speaking citizens of Montreal in the early years of the last century. These were the foundation of the Montreal General Hospital, the organization of the Montreal Medical Institution and the establishment by James McGill of his University.

The story goes back to the year 1819. Montreal was at that time a thriving little city of some 20,000 inhabitants, with a rapidly increasing English speaking immigrant population, among whom disease and destitution were distressingly prevalent, and with educational establishments and hospitals dating from the old French régime and adapted only to the needs of the French Canadian population, for whom also the latter provision was entirely inadequate. In that year the "House of Recovery" a small four roomed cottage which had been opened in the previous year 1818 by the Female Benevolent Society for

the care of the Protestant indigent sick, was replaced by a larger building situated on Craig Street and containing 24 beds, to which the name "*Montreal General Hospital*" was first given. It was provided with a code of regulations and an attending medical staff and "one Dr John Stephenson was installed as House Surgeon, to visit the Hospital every day in case of accidents."

From now on events moved quickly. The site of the present Montreal General Hospital was bought by private generosity in August 1820 and the Government was memorialized for support, on June 6, 1821, the corner stone was laid and on May 1, 1822, the central block of the present building erected by funds obtained from public subscription, was thrown open to patients, with an attending staff of the men already named with the addition of Henry P Loedel who resigned a few months later.

The Montreal Medical Institution. From the beginning it was clearly formulated that the hospital was to be used as the actual headquarters of a medical school and for the instruction of students, who were to be admitted freely to the wards for teaching and study. That this was understood as far back as 1819 is evident from the discussions in the House of Assembly in that year. Thus Dr Charles Perrault speaking in support of the motion introduced by Mr Molson for the establishment of a public hospital in Montreal, said "Independent of the good which must result from the establishment of a well regulated hospital to humanity at large, another no less important object is obtained by establishing in such an institution a school for teaching the healing art in all its branches." The initiative in teaching was taken by Dr Stephenson, whose name appears in the Hospital minutes on August 6, 1822 as receiving permission to advertise lectures for the ensuing winter in the subjects of anatomy practical anatomy surgery, and physiology with an introductory lecture to be delivered by himself at the hospital on October 7, 1822. Advertisements to this effect ran through the *Montreal Gazette* for the entire year, and the announcement of a course of 'experimental lectures on chemistry given by Dr Holmes at the house of Mr Alexander Skelton, appeared on December 14, 1822 and was continued until the following spring.

The first steps in the organization of the Montreal Medical Institution itself were taken on October 20, 1822 when at a meeting of the medical officers of the hospital held to consider the expediency of establishing a medical school in this city, Drs. Stephenson and Holmes were deputed 'to draw up the considerations that

seemed to warrant such an endeavour at this Hospital. This historic document was accordingly submitted a week later and approved. Its opening words are of great interest, as are also the references to the Edinburgh School and to the part which the new Institution was to play a few years later in the stabilisation of the infant college of James McGill. It read in part as follows:

The Medical Officers of the Montreal General Hospital, having seen the great difficulties which the student of medicine in this country has to encounter before he acquires a competent knowledge of his profession, knowing the great inconvenience resulting to many from the necessity at present existing of spending several years in a foreign country to complete a regular medical education, and being convinced of the advantage which would result from the establishment of a medical school in this country and considering that the Montreal General Hospital affords the student a facility of acquiring a practical knowledge of *Physic* never before enjoyed in these Provinces, an advantage which will be greatly enhanced by the establishment of lectures on the different branches of the profession, have met to consider of the possibility of founding such an institution in this city.

They consider that the Montreal General Hospital is an institution which favors much the establishment of a school of medicine in this city—it affords the student a facility of acquiring a practical knowledge of *Physic* never before enjoyed in this Province—an advantage which will be greatly enhanced by the establishment of lectures on the different branches of the profession.

They are further encouraged to attempt the formation of a medical seminary when they reflect that the medical school of Edinburgh, the basis of which they would adopt for the present institution, now justly considered the first in Europe, is of comparatively recent formation, it being little more than one hundred years since the medical lectures were first delivered in that city—and the early history of the Royal Infirmary of Edinburgh is not dissimilar to that of the Montreal General Hospital.

In the event of the establishment of a classical and philosophical seminary in this city the two institutions would be mutually benefited.

To ensure the success and permanency of such an institution it would be highly desirable that the persons composing it should be associated by a Royal Charter or Act of Incorporation.

On November 2, 1832 a copy of this Memorandum signed by all five members of the medical board of the hospital was forwarded the governor-in-chief, Lord Dalhousie, by Dr Robertson with a covering letter in which he suggested that in order to give the new institution legal status, the board of medical examiners for the District of Montreal should be reconstituted and made to consist of the medical officers of the Montreal General Hospital. Lord Dalhousie, whose enlightened attitude in educational matters was well known approved and on February 22 a Royal Commission was issued appointing 'the said Wm Robertson, William Caldwell, John Stephenson, A F Holmes and H P Loedel

any three or more of you to be the sole Medical Examiners for this District."

On February 4, 1833 an advertisement announcing the prospectus of lecture courses for the ensuing session 1833-34 for publication in the newspapers "of the Lower and Upper Canadas," was submitted to His Excellency and duly approved. It was headed "The Montreal Medical Institution" and after repeating the introductory paragraphs in the Memorial of Holmes and Stephenson upon the imperative necessity for the establishment of this School, it continued:

The circumstances which rendered the success of such an institution probable and the measures intended to be adopted for carrying the same into effect having been submitted to His Excellency the Governor-in-Chief, he was pleased to signify his entire approbation of the plans.

"It is therefore resolved to deliver lectures on the following branches of the profession to commence in the second week of November ensuing: *Anatomy and Physiology* J Stephenson, M.D. *Chemistry and Pharmacy* A F Holmes, M.D. *Practice of Physic* W Caldwell, M.D. *Midwifery and Diseases of Women and Children* W Robertson, M.D. *Materia Medica* H P Loedel, Esq. *Surgery* J Stephenson, M.D. In the course of the summer 1834 *Botany* A F Holmes, M.D."

Montreal, 4th February 1833

On August 23, 1833 following the resignation of Dr Loedel from the Board of the Hospital and Institution was received and Dr Wm. Lyons was appointed in his place, a medical library was established and an announcement of the lecture courses for the session 1833-34 to "commence at the House of the Institution No. 20 St James Street, was ordered published in the Montreal, Quebec, Kingston and Toronto papers. Figure 2 is a photostat copy of this advertisement from the *Quebec Gazette* of October 23, 1833. It effectually settles the date of the first session of the institution.

The original minute book of the Montreal Medical Institution containing all its proceedings and copies of correspondence with the Government during the 3 years of its organization has, fortunately for posterity, been preserved in the archives of the Faculty constituting its greatest treasure. These minutes were transcribed in part in an Introductory Lecture delivered at the opening of the session 1866-67 by Dr Archibald Hall¹ and they have been published in full by the writer² as an appendix to her "Historical

The Past, Present and Future of the Faculty of Medicine of McGill University By Archibald Hall, M.D. Esq., F.R.S.C. Professor of *Midwifery and Diseases of Women*, McGill University. Secretary of the *Quebec Society of Medicine*, Associate of the College of Physicians of Montreal, etc. *DEPOSED* Since 1867 also, Canada M. J. 1866-67, p. 31, 32, 33, 34.

An Historical Sketch of the Medical Faculty of McGill University By M. A. A. Abbott, M.A. M.D. Montreal, M. J. August, 1900 pp. 361-41. Also, *Quebec Printing Co.* pages, 10, 11, 12, Appendix 271, pp. 327-346.

Sketch of the Medical Faculty" which appeared in 1902

The matter of the incorporation of the Medical Institution was dealt with subsequently. In the summer of 1826, at the instance of Lord Dalhousie a form of charter was drawn up and presented through him to the Solicitor General for an opinion. The reply, received after a delay of 18 months, was unfavorable objections being raised on the ground that the school was not associated with any seminary of learning nor had it any endowment or foundation. After pleading in vain the similar beginnings of the College of Surgeons of London, Edinburgh, and Paris the officers of the institution suggested to the Government, as a means of obviating their difficulties, "the appointment of the members of the said Institution as Professors of the University to be established at Burnside, near that city one of the Colleges of which is established by Royal Charter, dated March 31 1821, and called the McGill College." As indicated previously this proposal came at the psychological moment for the young University of James McGill, and accordingly the memorable step was taken which gave the Medical Institution a charter and foundation and McGill an active and highly qualified medical faculty. As a result also the estate of Burnside was handed over to the university by the law courts in 1829 but the financial part of the bequest remained for several years longer in the possession of the contestant and residuary legatee, François Desrivières, the son of the widow of James McGill.

The Medical Institution as a Faculty of McGill
The first session in which the old medical institution functioned under its new guise as the Medical Faculty of McGill University was that of 1829-30, when it opened with the same teaching staff and some 25 students, its inheritance from the earlier school. The following year, on October 29 1831, a memorial was presented by its members to the Legislature asking that measures be taken to give effect to the authority granted by Royal Charter for the conferring of degrees to the candidates who had successfully passed the examinations and fulfilled the requirements of this school. On November 7 following the Solicitor-General advised that under its charter the university must first secure the royal sanction of its statutes. Two days later "the statutes, rules, and ordinances of the Medical Faculty of McGill University" was presented at Quebec in person by Dr Stephenson and forwarded to London. The reply, received on July 23 1832 conveyed His Majesty's approval of these stat

utes and sanctioned the conferring of the title of "professor" on all four members of the faculty. The first McGill degree was thereupon conferred on May 24, 1833 in medicine, on Mr W Logie. In that year also, the Governors passed a resolution "that the Medical Faculty be authorized to use all the means necessary to forward the suit now pending touching the ten thousand pounds bequeathed by the Honorable James McGill to this College," and appointed Dr John Stephenson university registrar. Shortly thereafter, the money so long withheld, was at last paid over with accrued interest. It now amounted to £22,000. Other changes promptly followed. Edinburgh which had from the first given official recognition to the Montreal Medical Institution by counting two of the latter's courses as equal to one of her own, now at once, on the joining of the school to the university in 1829 accepted the certificates of the faculty at their face value. The other British schools immediately followed this lead. Almost from the beginning also the obligatory course of study was changed to 4 from 3 years, each consisting of a 6 months session

THE FOUR FOUNDERS

Before proceeding to later developments a glance is necessary at the life history of the four men who figured so largely in the foundation of this school and university

William Robertson (1784-1844) who was called by his biographer¹ the Nestor of the famous quartette, was born at Kindrochet, Perthshire. He saw military service at a very early age, having been an ensign in a Highland regiment at the age of 13, and he qualified in medicine at Edinburgh while still under age. He came to Canada in 1806 and served through the War of 1812 in the capacity of surgeon to the 42nd Regiment, and he was present at the battle of Queenstown Heights and the storming of Fort Niagara. He retired from the army in 1815 and settled in Montreal and took, as we have already seen, a prominent part in the epoch-making educational developments of the next 30 years. He was a member of the Board of examiners from 1817 on and was from 1829 the official head of the Faculty and succeeded Dr Caldwell in the chair of medicine in 1833. He led the arduous life of a family physician with the largest practice in the city and was distinguished by his thoroughness and punctuality, generosity and charitable character which made him universally beloved.

William Caldwell (1782-1833) had been a surgeon in the 13th Regiment of Dragoons and was a veteran of the Peninsular War. He was born in Ayrshire and held the M.D. of Marischal College, Aberdeen University. Retired from the army after the War of 1812 he took out his license in the District of Montreal in 1817 and had settled in that city before 1819. His name is famous locally because of a duel which he fought in that year as the result of a quarrel with a Mr O'Sullivan who had opposed the petition presented in Parliament by the "Inhabitants of

SURGERY GYNECOLOGY AND OBSTETRICS

Montreal on February 19, 1819, praying for the establishment of an English public hospital. Both participants were wounded but recovered. Dr. Caldwell was the first lecturer on the principles of medicine in the McGill School. He served during the great cholera epidemic of 1832 but died of typhus contracted in the wards of the General Hospital in the following year.

Andrew Fernandez Holmes (1797-1866) is probably the most outstanding from the scientific standpoint of the four and with Dr. Stephenson has been universally considered one of the two real founders of the Faculty. He was born at Cadix, Spain, where his parents were detained as prisoners of war from a British vessel captured on its way to Canada where they arrived only in 1801. Given a good classical education at St. Skelton's famous school in Montreal, he was articled at the age of 14 to Dr. Daniel Arnold, known at that time as the dean of the profession in Lower Canada. Five years later in 1816 he presented himself for the Licentiate and in 1816 proceeded immediately thereafter to Edinburgh, and qualified by taking his diploma from the Royal College of Surgeons there in 818 and in 89 the degree of M.D. of that university. Along with John Stephenson he studied also in London, Paris, and Dublin. In 818-9 he was made an extraordinary member of the Royal Physical Society and in 830 a non-resident member of the Wernerian Society of Natural History of Edinburgh. An untiring worker in his profession, he was also an expert botanist and mineralogist and made large collections along both lines which are still housed in the University Museum at McGill, the Holmes Herbarium of Canadian Plants.

A catalogue of this was published by him in the vicinity of Montreal and represented the entire flora of the district. In the *Canadian Naturalist* for 1839, Dr. Holmes was also a scientific author of reports and has many articles in Polish and American as well as local journals, written in a polished style and classical English and based on accurate and discriminating observation of facts as to the Choleræ epidemic as it appeared in Montreal in 1834 and Cholera Diarrhoea as it appeared in Montreal in 1839. His articles on "Typhus Form of Cardiac Malformation" (published in the *Medical Journal*, 813, 8, 51-55, 210-218, and that on "Literature" in the *Transactions of the Edinburgh Medical Society* for 1834 are masterly productions. On his return from Edinburgh, Dr. Holmes was for 5 years in partnership with his former teacher, Dr. Arnold. At the organization of the Montreal Medical Institution he was appointed lecturer on chemistry and he held this chair of medicine. In 1853 he was elected the first president of the College of Physicians and Surgeons of Lower Canada and in 854 he became the first dean of the medical faculty of McGill University. He died in harness, when in the middle of calling a meeting for the latter. In 1864 this faculty established the Holmes gold medal which remains today the highest student award within its gift, in memory of their late dean, "than whom no man ever lived more conscientiously or died more beloved."

John Stephenson (1797-1842) The close friend and life long co-worker of Dr. Holmes, and, in the words of others we owe McGill College, "the man to whom above all others we owe McGill College." He was a native Canadian, having been born in Montreal. He was articled under Dr. William Robertson until July 1817 when having finished his apprenticeship he joined Holmes in Edinburgh. He took his degree of M.D. from that University in 1830, having meantime qualified for the license of the Royal

College of Surgeons in London in 1819. On returning to Montreal in 1821 he immediately entered upon a large practice as a surgeon and he lectured on this subject and on anatomy at the medical school from 1823 to 1835 and after this on anatomy alone until his death. As secretary of the medical institution and faculty from their inception, and repatriator of the university itself from their inception, devoted service and it was universally recognized by his contemporaries that the successful issues to the university of the contest over the will of James McGill was chiefly if not entirely due to his energy and influence. He was a man of culture and of great industry and integrity and an enthusiast in the cause of medical education. As a surgeon of experience he had the confidence of the public and his name is said to have become in this regard as a household word in the homes of all nationalities in this city.

PERIOD OF GROWTH AND DEVELOPMENT

The tragic death of Dr. Caldwell from typhus, in 1833 made the first break in the ranks of the four veteran teachers. The gap was temporarily filled by Dr. John Racer, and on his removal to Quebec 2 years later in 1835, by the appointment of G. W. Campbell to the chairs of midwifery and surgery and Archibald Hall to that of materia medica. Both these men were graduates of Scottish Universities, Dr. Campbell of Glasgow, and Archibald Hall an M.D. of Edinburgh and their activities in the succeeding 30 odd years were probably the most essential factors in the rapid expansion and stabilization of the medical school that now existed, and in the organization of the Canadian medical profession on a conservative educational basis. Dr. Campbell held both his chairs until 1842 and then resigned from midwifery but retained that of surgery which he filled until 1875 a period of 40 years. As a member also of the visiting staff of the Montreal General Hospital during this entire time, he is said to have had the foundation, by his great skill and distinguished abilities, of his high reputation enjoyed by this hospital as a school of practical surgery. In 1860 he succeeded Dr. Holmes as Dean, an office he retained until his death. Dr. Archibald Hall (1812-1868) was likewise transferred in the reorganization of the faculty that took place in 1842 on the death of Dr. Stephenson and the retirement of Dr. William Robertson to the chair of chemistry and in 1854 he succeeded, on the death of Dr. McCulloch, to that of midwifery a position to which he had been specially trained, having served his apprenticeship under accoucheur of his day Dr. Hall's most important contribution lay however in the field of medical legislation and Canadian medical journalism of

Portraits of three of the four founders of the Montreal Medical Institution and medical faculty of McGill University from oil paintings in the possession of the McGill medical faculty and signatures of the four founders of the medical faculty: W. Caldwell, M.D. (1783-1833), A. F. Holmes, M.D. John Stephenson, M.D. and W. Robertson. (From their Memorial dated October 29, 1831 praying that the governors of McGill College be given authority to confer degrees.)

which latter he may be said to have been the founder. A keen and incisive writer with a clear sense of educational values and a determined though generous opponent of what he considered professional irregularities, he took a leading part in the bitter medical polemics of the day that waged, especially in the years 1847-51 about the rights or otherwise of incorporated medical schools to confer diplomas carrying the right to the license to practice without further examination or university degrees. As editor and owner from 1845 on of that grand old periodical the *British American Journal of Medical and Physical Science* he fought in this and other ways the battle of his college and of the profession at large and became the intrepid defender of the rights

and interests of both. In 1855 he was made vice president and in 1859 president of the "College of Physicians and Surgeons of Canada East" whose Act of Incorporation and Charter he had guarded so vigorously and well. He was also an honorary fellow of the Royal Obstetrical Society of London and an associate of the College of Physicians of Philadelphia.

The real growth of the medical school did not begin until 1841-42 when the yearly attendance of students, which had averaged 25 up to this time, rose to an enrollment of 39. For some time thereafter progress still remained slow, there being only 44 students in 1849-50. In 1850-51 however, there were 53 enrollments and from then on the numbers advanced steadily to 108 students

MONTREAL MEDICAL INSTITUTION

THE Lectures will commence at the House of the Institution, No 20 St James Street, on MONDAY the 20th of November at 1

Maternity, 31 Dec. and Obstetrics, Thursday 11th, at 9 A. M.
 P. M. 11 O'N. E. P.

Midwifery and Diseases of Women and Children, Wednesday
 12th at 2 P. M. W. H. HOLMES M. D.

Lectures on Friday will given by Dr. HOLMES, during
 the Summer.

✓ B - Visiting lectures at the Montreal General Hospital &
 Yacht - 11th October

Fig 3. Advertisement from the *Quebec Gazette*, October 13, 1853, announcing the first courses of the Montreal Medical Institution for the ensuing session 1853-54. (The sign "B" written across this advertisement was inscribed by the publishers of the paper and indicated that the charge for its insertion was one shilling.)

in 1859-60 141 in 1869-70 166 in 1879-80 261
 in 1889-90 312 in 1893-93 401 in 1894-95 and
 650 in 1902-03. At the present time under the
 limitation of the yearly registration to 100 stu-
 dents, the enrollments at the opening of the
 present session 1934 35 numbered 480.

The decided impetus that thus took place in the middle of the last century may be ascribed to three different causes. First of these was the growing superiority of the clinical teaching consequent on the activities of an enlarged and competent hospital staff among whom must be especially mentioned Robert L. Macdonnell a licentiate of the Royal College of Surgeons of Ireland who though only 5 years on the staff of hospital and college left upon these a lasting impress. Trained in the distinguished school of clinical medicine of the Meath Hospital in Dublin where he served under the celebrated Graves and Stokes, he became deeply imbued with their teachings and added to a familiarity with the current medical literature and an intimate knowledge of the methods of investigating disease a valuable practical experience gained in their wards as an assistant of these great clinicians. On his appointment to the staff of McGill in 1845 he immediately set about introducing their methods at the Montreal General Hospital with a contagious enthusiasm that quickly resulted in the reorganization on a permanent basis of the teaching in clinical medicine along lines that placed the McGill School on a plane with the most advanced European and American institutions. Other factors of importance in the acquiring of this reputation were the eminence already referred to above, of G. W. Campbell as a teacher

skilled in the practice of surgery of Drs James Crawford and Sewell in clinical medicine, as also the brilliant William Sutherland and last but not least the sterling qualities of Dr Michael McCulloch of Glasgow an L.R.C.P. of London and an honorary M.D. of McGill, who was professor of midwifery from 1842-54, and who in those pre-aseptic days was yet able to reduce the mortality at the Montreal Maternity Hospital to 1 death in 354 cases.

No less important was the emergence at this time of the University itself from the depression that had until then engulfed it, to an era of relative prosperity and financial security under the powerful administration of McGill's first great principal, Sir William Dawson, whose appointment dates from October 1855. From the first he took a highly constructive interest in the medical faculty. The appreciation with which he viewed its pioneer labors was expressed in his inaugural discourse at this time as follows:

"It is second to none in America and presents one of the noblest instances anywhere to be found of the results which may be attained by the almost unaided exertions of able men thoroughly devoted to their work. Its announcement for the present session (1855-56) shows a staff of 12 Professors, a library of 5,000 volumes, an extensive series of Museum preparations, and excellent arrangements for hospital practice and dissection. It has sent forth since the conferring of its first degree in 1833, 150 graduates. Nothing in connection with education in this city offers more just cause of pride or hope for the prosperity of our Institution than the success which has attended the labors of the Medical Faculty."

The third element in the expansion of the Faculty which began with the sixth decade of the last century and has never ceased up to the present time is described in some detail below. It was the removal of the school to a more convenient location in the vicinity of the hospital and to the occupation of a building in its own personal possession, the old Coté Street School.

THE BUILDINGS OCCUPIED BY THE MCGILL MEDICAL SCHOOL

The first lectures were delivered, as its advertisements state (Fig 3) at the house of the Institute "No 20 St. James Street, a small building (Fig 3) on the north side of what is now Place d'Armes Square. The School remained here for some years and then removed to a tall narrow building on Fortification Lane just behind the present Bank of Montreal. Later some time after 1833 the Faculty established itself in a large three story brick building which is still standing on the west side of St. George Street, three doors above Craig Street. The accommodation here

Fig. 3 "No. 20 St. James Street" believed to be the first home of the Montreal Medical Institution and the medical Faculty of McGill University. (From a drawing by Professor J. C. Simpson, in the possession of the Historical Medical Museum of the School)

Fig. 4. The Coté Street Building, owned by the Faculty of Medicine and occupied by it from 1851 to 1872. It was from this building that William Osler graduated in the spring of the latter year

seems from the first to have been unsatisfactory but the question of ways and means was at this time of paramount importance. It was probably on this account that the medical faculty was invited to occupy in the year 1845 the Arts building of the university itself erected in 1843 and the only one except the principal's office then standing. The first session of the medical school in the college building was that of 1845-46 and there it remained for the 5 succeeding years. During this time the student body suffered greatly under the inconvenience of the location which at that time lay far out in the country for the university grounds were a mile and a half beyond the city limits. A lecture at the college ending at 12 noon a rush through often untravelling winter snow and a vain attempt to dine and attend a one o'clock clinic at the Montreal General Hospital were a daily trial even to the bravest as also were the eight o'clock morning lectures, to be reached frequently only through almost impenetrable snow drifts, and the attendance by night in the dissecting room on the top floor of this lonely building which lay far removed from other dwellings and was lighted only by candles. On March 19, 1847, the students set forth these disadvantages in a petition asking that the lectures be again given in town. Action was not taken, however until the spring of 1851, when the St. Lawrence School of Medicine, a rival institution

with headquarters in the city, was organized. The McGill School then decided to leave its out-of-the-way situation and return to town rather than risk competition under such unfavorable circumstances. Three members of the faculty, Drs. Campbell McCulloch and Sutherland accordingly undertook to erect a suitable building at their private expense and to rent this to the faculty, the rent received to be 10 per cent on the outlay and the faculty to pay the assessments. The lot purchased for the purpose was on the east side of Coté Street in the close vicinity of the Montreal General Hospital, and a brick building, No. 15 Coté Street, was promptly erected upon it, in time for the opening of the session 1851-52. Here the school remained until the autumn of 1872, and here during these 21 years passed in an unbroken circle of steady work and gradual progress, the sure foundations were laid for the later era of relative prosperity that ensued. Here in 1853 all ten of its lecturers were appointed professors, and here in 1854 Dr. Holmes became its first dean. New appointments were made and new courses opened, examinations divided into primaries and finals, a summer session established and the number of students rose from 64 in 1851-52 to a roll-call of 184 in 1866-67. Here Dr. R. Palmer Howard, professor of medicine and dean of the faculty from 1882 on, by his

Fig. 5 The first building of the McGill medical faculty in the University grounds. Erected in 1871 and destroyed with its extensions by fire in 1907.

sound and up-to-date teaching at the bedside in close correlation with the autopsy findings inspired with his own zeal a galaxy of youthful intellects, and gave the first impetus to the foundation of a chair of pathology. Here Osler graduated, George Ross and Richard L. Macdonnell taught, and F. J. Shepherd was an undergraduate—members all of a group of eager young clinicians who were a few years later to take a leading part in the coming of age of scientific medicine and surgery on this continent.

In the year 1860 the university took over the Coté Street building and made extensive improvements in it at a total outlay of £9,360 of which £1,200 was paid the proprietors for its purchase and the balance expended on the enlargements that had become necessary. The number of students continued to increase steadily however and again overflowed its capacity so that further space became again essential. And now the faculty themselves began to look upon the university grounds as their proper home. The rapid growth of the city to the westward had removed the old objections to this location, and even rendered it a more suitable spot than a place nearer the hospital, in what promised to become one of its poorer quarters. Accordingly after considerable preliminary negotiation the university decided in the year 1871 to build within its own precincts for the accommodation of its medical faculty. Accordingly a square stone building of commodious proportions was erected by the Governors at a cost of \$27,000 on the University Street side of the college property and thrown open for occupation in the autumn of 1872 (Fig. 5). Most of the university funds had been de-

rived from the sale of the historic Burnside House, the faculty on its side binding itself to keep the building insured up to \$16,000 and to pay all assessments, taxes, and repairs.

The material advancement of the School after this epoch-making step is measured by the extensions of this modest single block of 1872 through three successive additions—that of 1885 for the accommodation of 300 students, that of 1895-96 for the establishment of pathological and public health laboratories to the fine new building of 1902 (Fig. 6). Funds for these operations were obtained from the Lean Choi endowment of \$50,000 given by Lord Strathcona in 1882 and the G. W. Campbell Memorial Fund of \$50,000 raised among graduates and friends of the University in 1883 from \$60,000 contributed by Mr. J. H. R. Molson in 1893 for building and equipment of the laboratories, rendered necessary by the endowment earlier in the same year by Lord Strathcona of the chairs of pathology and public health with \$100,000. In 1899 the same generous donor contributed another \$100,000 and this together with \$3,000 from the faculty funds was all expended upon the construction of the "new" building or extension of 1901-02.

In 1907 this fine Medical Building the pride and joy of the Faculty was destroyed by fire, the only part remaining intact being the extensions for laboratories and lecture room at its rear and the library and historical part of the Museum. In 1911 the present "Strathcona Medical Building" was erected from funds obtained from the fire insurance and \$450,000 from Lord Strathcona, on a site farther up on the hillside commanding a fine view of the city and in closer proximity to the Royal Victoria Hospital which institution had been founded under the aegis of the university by Lord Strathcona and Lord Mount Stephen in 1894. This "new Medical Building," a handsome stone structure of modern construction, was made to house the administration offices, library and museums, and the departments of anatomy, pathology, pharmacology and public health, the other parts of the school being taken care of in the parts of the older building that had escaped total destruction and which were temporarily repaired for the purpose.

THE PRESENT ERA OF EXPANSION

The new building of 1911 was erected and opened under the able administration of Dr. F. J. Shepherd (1851-1929) professor of anatomy for the 30 years from 1883 on and dean of the faculty from 1908 to 1914 whose eminence both as a surgeon and educationalist were important

Fig. 6. The New Building of 1902, showing that of 1872 forming its first block, and behind this the extensions made in this and the previous year. The front and middle parts of this building were destroyed by fire in 1907.

factors in the advancement and growing reputation of the school, and were acknowledged by the conferring upon him of the honorary fellowships of the Royal College of Edinburgh and London and the honorary LL.D. of Harvard. This year 1911, marked also the commencement of what has been termed a golden age for McGill for in the 23 years that have elapsed since, an immense expansion has taken place largely in the direction of medical research, the first impetus to which may be said to have been given by the work of Wyatt Johnston (1860-1902) and Prof. J. G. Adams (1862-1926). During the last 15 years, that is, since the appointment as principal in the year 1920 of the late General Sir Arthur Currie with his fine spirit and splendid initiative force, and in 1923, as dean of the faculty, of Dr. C. F. Martin whose gift of organization and distinguished services to the cause of medical education were recently recognized by Harvard University by the conferring upon him of its honorary LL.D., this expansion has become nothing short of colossal. So swift indeed has this been alike in new departments organized, in generous benefactions received and in the appointment of men endowed with the spirit of enquiry and the faculty of leadership that a mere enumeration of these events is almost beyond the compass of this article. However, the contrast with the day of small things described above is so picturesque and the

outcome of the latter has been so spectacular that an outline must be attempted here.

Financial support was supplied in 1911, by the Robert Reford Endowment of \$100,000 for the department of anatomy and by the establishment of the Arthur A. Browne (\$10,000) and the James Douglas (\$35,000) research fellowships, in 1912 by the gift of \$14,000 for the establishment of the Eddie Morrice Laboratory of Pharmacology, in 1913, by the gift of \$12,566 subscribed by the friends and graduates of the medical faculty to meet the fire loss of 1907. In 1917 by the George Ross Endowment Fund, in 1919 by the bequest of Sir William Macdonald of \$500,000 to the funds of the faculty, a year marked also by the invaluable gift of the Osler library bequeathed to McGill on the death in that year of its beloved owner and founder. In 1921 came the great centenary celebration when \$6,000,000 was given to the University, of which \$4,000,000 was subscribed by the graduates and friends of the Institution, \$1,000,000 was given by the Province of Quebec, and \$1,000,000 was donated from the Rockefeller Foundation, the latter sum being a grant for the special uses of the medical faculty. In 1922 the Biological Building, erected on the site of the original medical building destroyed by fire, was opened housing the new department of biochemistry in which the researches of Prof. J. B. Collip and his associates have brought such

Fig. 7 The Strathcona Medical Building erected in 1911 and in occupation today. Contains the administration offices, medical and Osher libraries and museums and the departments of anatomy, histology and public health.

well deserved fame to the School in 1923 was built the fine Pathological Institute. In 1924, the University Clinic for Researches in Internal Medicine was established under the direction of Prof. J. C. McEakins, with the help of a grant from the Rockefeller Foundation of \$500,000. In 1925 came the erection of the Royal Victoria Montreal Maternity Hospital with accommodation for 200 patients and presenting the last word in equipment, under Prof. W. W. Chipman. A department of child study was instituted with the help of a grant of \$56,500 from the Laura Spelman Rockefeller Memorial Fund. In that year also the departments of public health and preventive medicine were united under the directorship of Prof. Grant Fleming, whose wide contacts with every health organization in the city as well as on the National Committee of Mental Hygiene, and as a member of the Advisory Health Board of the city make this a center of far reaching influence. In 1927 a subdepartment of industrial medicine with an industrial clinic at the Montreal General Hospital was established by a grant from the Metropolitan Life Insurance Company of \$25,000. In 1928 the department of bacteriology was recognized as a separate chair and has acquired in the person of Prof. E. G. D. Murray

of Cambridge an occupant of international fame. In 1929, a laboratory for experimental surgery was built and equipped by friends of the Faculty and \$85,000 was donated by the Rockefeller Foundation for surgical researches therein. During 1932-33 an additional \$100,000 was granted from the same source to maintain the research activities of the department of neuro-surgery.

Finally there has but now come to pass, as the crowning event of the benefactions listed above in the opening on September 27 last of the Montreal Neurological Institute under the direction of Profs. Wilder Penfield and W. V. Cone, what may well be described as the best and noblest achievement in the history of McGill's great Faculty. Just as, long ago in the stillness of the committee room of the old Montreal General Hospital, measures were promulgated and activities instituted by public spirited men of vision that gave birth to a great educational movement, so today the hour has once again struck, and opportunity has met, upon its crest, the men. Dr. Penfield was "enticed" to McGill in the year 1928, on the initiative of Dr. E. W. Archibald, professor of surgery, under the promise of financial support from a few public spirited citizens and the help of the research funds of the

faculty, and in company with his devoted associate Dr W V Cone. Immediately on arrival they organized an effective laboratory service within the necessarily restricted space available, and instituted an extremely active neurosurgical service with headquarters at the Royal Victoria Hospital, but having relations with practically all the hospital units in the city. The creation of the present magnificently equipped neurological Institute has been the result of incessant labor of all concerned in the 6 intervening years and was made possible by large endowments for its building and upkeep, which include a grant from the Rockefeller Foundation of \$1,232,650 and liberal yearly grants of \$15,000.00 from the City of Montreal and \$20,000.00 from the Province of Quebec as well as munificent gifts from several private donors—Sir Herbert Holt, Mr J W McConnell, Mr Walter Stewart, and four others who wish to remain anonymous. The Institute is thus a civic, national and international

affair, in affiliation with McGill but independent of it in funds, and functioning for the benefit of the community at large without restriction of place or creed. None who had the privilege of taking part in the great function of its inauguration, of listening to the first neuro-surgical foundation lecture by Dr Harvey Cushing and the addresses of Drs. Gordon Holmes, Martin Archibald, and others and Dr Penfield's own clear cut utterances on that occasion and who had surveyed the perfect adaptation of the building and its contents to the objects in view, can doubt that there is here developed on a sound and enduring basis an international center, in which the study and practice of clinical neurology and neurosurgery together with scientific investigation in these fields on the highest plane of inquiry, will combine to shed light over this entire continent and to introduce a new era in the understanding and treatment of these most obscure and potentially tragic of all human disorders.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE monograph on the lymphatics¹ by Drinker and Field, comprises 254 pages of well printed material, on pages 5 by 8 inches, bound in rigid covers. The authors state "The data presented is drawn from anatomy physiology pathology and immunology. We have wanted to give a working idea of what the lymphatics are steadily engaged in doing in the mammalian body. The first chapter of 12 pages is given to the structure of the lymphatic system and the next section discusses the entrance of foreign particles and colloidal solution into this system. The normal permeability of the blood capillaries and the balance of forces between the capillary blood and the tissue fluid is given considerable space. The authors state that the blood capillaries are the essential mechanism for determining the water content of the tissues. Lymphatic drainage, by keeping down the concentration of protein in the tissue fluid, affects water absorption but the actual instrument in accomplishing water balance is the blood capillary. The composition and flow of lymph are discussed. One of the principal interests of the authors was the problem of the relation of lymph to the fluid which actually bathes the tissue cells and in which the physiological reactions of the body occur. Capillary lymph and tissue fluid are considered to exist in a common reservoir and to this the blood capillaries make additions of fluid and withdraw it by reabsorption. Experimental and practical considerations comprise the second half of the book. An extensive bibliography and a nice review of the literature is given as the authors cover this subject in a scholarly and conservative manner.

M. H. BAKER

THE *Atlas of Pathological Anatomy*² compiled by E. K. Martin has been issued under the direction of the editorial committee of the *British Journal of Surgery*. This, the first volume, is made up of fasciculi published in the *British Journal of Surgery* during the years 1926 to 1930 inclusive and is the first of a series of such volumes which are intended to appear from time to time until it includes all such subjects as can profitably be illustrated by drawings of museum specimens, without attempting a reproduction of the rarities and curiosities of sur-

gical practice. The late Sir Anthony A. Bowlby in his introduction to the *Atlas* has emphasized the fact that illustrations cannot hope to replace the actual examination of specimens, but has expressed the hope that such illustrations will act as a stimulus and guide to the present day surgeon who too often relies entirely upon the opinion of a trained microscopist.

The arrangement of the material within the book is somewhat unusual in that it does not follow the various systems nor the classifications of general pathology. Thus, the book starts out with three sections dealing with bone tumors and ends up with a section on inflammation of bone, while between the first three and the last section are sixteen other sections dealing with the stomach, the breast, the kidney and the gall bladder and bile tracts. It is conceivable that if such a lack of arrangement obtains throughout the series, the surgeon who has to deal with an obscure bone lesion may have to scan through several volumes before he secures a comprehensive presentation of gross bone pathology. Even in this one volume the comparison of neoplastic with inflammatory bone disease requires turning from one end of the book to the other and still the whole of bone pathology amenable to illustration would not be covered.

The material presented is excellently illustrated, and especially pleasing are the numerous colored plates which are beautifully executed and reproduced. The specimens are carefully selected to show the more usual conditions with which the surgeon comes in contact and to depict those stages of the condition which are usually seen by the surgeon. Particularly excellent and especially valuable to the practicing surgeon is the section of 95 pages which deals with diseases of the breast. We find here page after page of illustrations of gross and microscopic appearances of benign and malignant conditions of the breast, accompanied by short clinical histories of each specimen.

Each section is headed by a short succinctly written introduction which covers, in a surprisingly thorough fashion, the important details of the pathological anatomy and histology. MICHAEL I. MASCO.

ABOUT one-third of this volume³ of 400 pages by Pemberton and Osgood is devoted to the influence of the fundamental sciences on our knowledge

¹LYMPHATICS, LYMPHS AND TISSUE FLUID. By Cecil K. Drinker, B.S. M.D., and Madeline E. Field, A.B. Ph.D. Baltimore: The Williams & Wilkins Co. 1931.

²ATLAS OF PATHOLOGICAL ANATOMY. Issued under the direction of the Editorial Committee of the *British Journal of Surgery*. Compiled by E. K. Martin, M.B. F.R.C.S. vol. Baltimore: William Wood & Company 1931.

³THE MEDICAL AND ORTHOPAEDIC MANAGEMENT OF CHRONIC ARTHRITIS. By Ralph Pemberton, M.S., M.D., F.A.C.P., and Robert B. Osgood, A.B., M.D., F.A.C.P. New York: The Macmillan Co. 1934.

of joint disease. The etiological factors, local and general, are discussed at length and the symptomatology and treatment are presented admirably. The work is divided into 14 chapters, with a bibliography appended at the end of each chapter. This makes it valuable as a reference, for the outstanding work in the world literature of joint disease is included.

In the preface, the authors condemn the unjustifiable pessimism toward arthritis which is extant in many quarters of the medical world today. They believe that such an attitude has been an important factor in delaying the advent of adequate therapy in this field. Certainly this is true, as those of us who see a great deal of arthritis know, and the physician who with a shake of the head, allows a patient with this disease to progress to the state of an arthritic derelict assumes an enormous responsibility.

To me the most interesting and instructive part of the book is that devoted to the fundamental sciences. The newer aspects of normal and abnormal joint physiology are well presented, and the text and illustrations of joint pathology are in every sense adequate. For better illustrations from the standpoint of detail one may look to the similar work of Allison and Gbormley (William Wood & Company).

The treatment of arthritis, as the title of the book implies, is considered under the heads of medical and orthopedic management. None of the methods advocated is essentially new, but the comprehensiveness with which the authors present this phase of the subject makes the work a valuable adjunct to the practitioner's library. The subject of the theory and practice of drugs, vaccines, and physical therapy is included as well as of conservative and operative orthopedic treatment.

While the authors intend this book principally for practitioners, I think it desirable for the use of students in their clinical years. With their courses of pathology and physiology just completed this book, with its specialized point of view, should give them a valuable insight into the nature of arthritis. The treatment as outlined, and the associated references, should enable them to appreciate the possibilities of helping arthritis, which is in the larger sense the purpose of this book.

PAUL B. MAGNUSON

THE conception of the fundamental radiological principles on which the diagnosis of various gastro-intestinal lesions must be based is described and analyzed by the Cole collaborators in their recent work.¹ The anatomical, pathological and roentgenological findings are correlated. The book was not intended to be a text on gastro-intestinal X-ray diagnosis. Dr. Cole's originality and resourcefulness is amply displayed not only in the device of apparatus for carrying out his original technical

ideas, but also in his ingenious adaptations of line drawings and photographs and the interpretation of roentgenograms. The authors have advanced a number of original theories and interpretations, some of which are at variance with the ideas of well known physiologists and some of the previously published work from abroad but indeed Dr. Cole makes no positive claim to be correct, simply leaving the reader to draw his own conclusions. The pages of this work represent an enormous amount of labor unselfishly devoted to the elucidation of some important gastro-intestinal problems. Its chief value lies in this praiseworthy attempt to open up to more general recognition the radiological interpretation of findings in the small intestine.

With reference to the technique, attention is drawn to the emphasis, laid especially in Europe upon relief studies of the digestive tube. Much stress has been laid upon localized pressure applied with a compression bag or similar means. The authors make the significant statement that they have yet to see a single case in which localized pressure has established the diagnosis of any ulcer of the duodenum or any other organic lesion of the stomach where the diagnosis has not already been established by the serial routine method of examination in common use in this country.

In systematizing the interpretation of gastro-intestinal screen and film findings, studies were directed to the following 4 fundamental findings which Cole advances as the criteria for exploring the mucosa of the digestive tract: (1) the lumen of the tract viewed in profile, (2) special folds of the mucosa viewed on edge, (3) pliability of the mucosa to peristaltic contraction, (4) the pattern of the mucosal folds or rugae.

JAMES T. CASE

ANOTHER of the series from the Oxford University Press on medical disorders is presented by Platt in a volume of 166 pages,² in which he discusses nephritis and allied diseases. The author states that the book is not intended as a first introduction to the physiology or pathology of the kidney but rather for the senior student or practitioner who is, of course, assumed to have a certain familiarity with the clinical conditions of oedema, high blood pressure, albuminuria and the like, and to have seen cases of nephritis in the hospital wards or in practice.

The theory of filtration and differential absorption has so much evidence to support it that it may be accepted provisionally as correct, especially since the researches of Richards and Wearn. Chapters I and II however are given to a simple discussion of structure and function of the kidney together with functions in disease. Chapter III deals with a discussion of urine examination and renal function tests. A very simple practical explanation for the author's classification of renal disease follows.

Nephritis and nephrosis are used in a broad sense

¹RADILOGICAL EXPLORATION OF THE MUCOSA OF THE GASTRO-INTESTINAL TRACT. By the Cole Collaborators. Lewis Gregory Cole, M.D., Robert E. Pezard, M.D., William Gregory Cole, M.D., Russell E. Morse, M.D., Courtney I. Hendland, M.D., Ames William Nordend, M.D. St. Paul and Minneapolis. The Bruce Publishing Co. 1934.

²NEPHRITIS AND ALLIED DISEASES, THEIR PATHOLOGY AND TREATMENT. By Robert Platt, M.D. (Sheff.) M.R.C.P. (Lond.) London: Oxford University Press, 1934.

as denoting the more inflammatory and the more degenerative forms of Bright's disease, respectively and as degenerative changes are always present in nephritis, there is no valid objection to looking upon nephrosis as a sub-variety of nephritis, the term denoting not cases showing tubular degeneration but rather cases in which inflammatory changes are inconspicuous." It seems to the author wrong to make too sharp a distinction between lipid nephrosis and subacute nephritis since both commonly arise in connection with some septic process in the body. Nephrosis may therefore, be looked upon as a variety of subacute nephritis in which some of the

signs are minimal or lacking. The arterial and sclerotic cases are placed in a group called nephrosclerosis. A small section is given to renal dwarfism and polycystic kidneys. The sections on treatment are concise and they are stated in a practical manner.

This treatise on the whole seems to be a good discussion of medical diseases of the kidney. A broad, constructive viewpoint obtains which gives the feeling that the author has had a substantial experience in the field of renal disease. The sections on treatment are up to date and practical. This little volume should be of assistance both to the student and the practitioner.

PRINCIPLES OF GASTRIC SURGERY¹

DONALD C BALFOUR M.D. F.A.C.S. ROCHESTER, MINNESOTA
Mayo Clinic

THE American College of Surgeons in this annual lecture keeps before its Fellows the life and work of John B. Murphy. Previous lecturers from this country and abroad have rendered tribute to those extraordinary talents through which Murphy attained great eminence and have discussed the contributions through which this master surgeon was such an important factor in elevating American surgery to the position which it has attained. It is therefore at once an honor and a responsibility to join in the commemoration of a founder of the College who created for himself a permanent place in the history of surgery and of surgeons.

The evaluation of Murphy's writings arouses amazement for it seems inconceivable that with facilities which the surgeon of today would consider meager and inadequate Murphy could have made so many classic contributions which time has confirmed. The surgical treatment of pulmonary tuberculosis of trigeminal neuralgia of lesions of bones and joints of genito-urinary disorders and of intra abdominal conditions, particularly acute appendicitis, tuberculosis of the fallopian tubes, and lesions of the gastro-intestinal tract are a few illustrations of the wide interests of his inquiring mind and of the range of his accomplishments.

The progress of surgery since the time of Murphy has been, and will continue to be in specialization and it is doubtful if any sur-

geon of the future ever will equal him in the originality of the investigations which he made in so many different fields. He possessed that uncommon quality of maintaining both an intensive interest in a subject and a determination to know the truth until by persistence and rare clinical experience and judgment he effected its highest possible development. Putti referred to Murphy as "perhaps the last of a generation of general surgeons who are able to cope with the whole field of medical practice in all its complexities and who have laid the foundation of modern specialization." With his ability to solve the intricate surgical problems of his day he acquired the art of imparting his knowledge to others in a superlative degree and became recognized by surgeons of all countries as the greatest teacher of surgery of his time. To those who had the privilege of attending his clinics the name of Murphy will always be an inspiration and the American College of Surgeons, through this memorial lectureship, will carry on to coming generations the influence derived from a contemplation of the life of this master surgeon.

Inasmuch as not the least notable of the contributions of Murphy are to be found in his published works on diseases of the stomach and duodenum, a brief consideration of the evolution of the principles underlying gastric surgery would seem appropriate to this occasion.

¹The John B. Murphy Oration on Surgery presented before the Clinical Congress of the American College of Surgeons, Boston, October 5, 1934.

One of the fathers of modern surgery was Theodor Billroth of Vienna. His clinic, like Murphy's, became a Mecca for students of his day and much of the impetus to American surgery can be attributed to Billroth and his school. He was the first to resect the stomach successfully. As Wiess wrote, "There was nothing accidental in its success. Months of hard, persistent study preceded the attempt, the pathology of gastric carcinoma was thoroughly reviewed, statistics were scrutinized from every angle and an entirely new technique had to be devised and practiced." It is interesting to note, as Finney pointed out in a review of the history of gastric surgery that the great surgeon Langenbeck, only a few years before Billroth performed a resection of the stomach, had said "I look upon this operation as a quicker method of sending out of this world a man whom it is impossible to save." Contrast this with Billroth's prediction that every surgeon who has had experience in experiments on animals and similar operations in men has reached the conviction that resection of the stomach must and will succeed. Finney rightly emphasized the part of experimentation on animals in this development since it was the practice of these pioneer surgeons carefully to plan carry out, and study the results of operations on animals before employing them on men. Billroth was a pioneer in surgical pathology and made many contributions in this field, but his greatest legacy was his pupils, who were called to fill many of the chairs of surgery not only in Austria, but also in Germany. Murphy always gratefully acknowledged that his methods of clinical investigation were based on what he had observed in Billroth's clinic, and that he owed much of his knowledge of clinical teaching to Professor Albert of Vienna, a contemporary of Billroth.

To the influence of Billroth and his pupils, therefore, may be attributed the progress of gastric surgery and the rapidity of this progress is extraordinary in view of the status of abdominal surgery before this period. The development was characterized by the evolution of technical methods, to the end that operations for lesions of the stomach and duodenum could be safely performed. In this

evolution American surgeons have had a large part. General principles of management soon became established, and various technical procedures were developed to deal effectively with the variabilities of benign and malignant lesions. Attention was directed primarily toward security of suture lines and to this end attempts were made to eliminate the "fatal suture angle" of the original Billroth I resection (end to-end, stomach to duodenum) and to prevent mechanical complications. The problems involved in accomplishing these purposes are evidenced in the many modifications of operations on the outlet of the stomach, of reconstruction operations for gastric resection, and of gastro-enterostomy. The history of gastro-enterostomy is a conspicuous example of the development of gastric surgery during this early period for the causes of the mechanical defects, which at first almost prohibited performance of the operation became known, and the operation was so modified that now such complications are rarely encountered when the indications for the operation are clear and it is properly performed.

The menace of anastomosis by suture, however still retarded the advance of gastro-intestinal surgery and a variety of mechanical devices, such as bone plates, were advocated to cope with this danger. None, however proved satisfactory until Murphy in 1892 announced the invention of a metal button for accomplishing quick and secure anastomosis between segments of the gastro-intestinal tract. This instrument became known as the Murphy button and the evidence soon was conclusive that in respect to safety it was superior to the suture as then employed. This offered a challenge to those who were striving to perfect methods of suture, for the disadvantages of the introduction of a non-absorbable foreign body were obvious if some procedure equally safe and not requiring the use of non-absorbable material could be devised. The place of the Murphy button in the evolution of gastro-intestinal surgery especially in those portions of the intestinal tract in which infection is a particular menace, is manifested in the methods still being devised to what Murphy accomplished with the button namely aseptic anastomosis.

The primary impetus to gastric surgery, therefore, was the perfecting of technique to a point at which operation could be carried out with minimal risk. The secondary, but no less important, impetus came from the spectacular results following the surgical management of lesions of the stomach and duodenum and of their complications. The revelation that surgical intervention usually could accomplish permanent cure of such a chronic disease as gastric or duodenal ulcer, could cure a definite percentage of cancers of the stomach, could save the life of the patient with an acute perforation and could permanently relieve benign obstructions, marked one of the great advances of modern medicine.

The success with which surgery met such conditions led naturally to efforts to employ surgical treatment in the earlier stages of disease. In the case of carcinoma of the stomach, such efforts were well founded and have definitely increased the operability of the disease. In the case of ulcer however, the apparent desirability of earlier surgical management unfortunately led not only to operation being carried out for lesions not suitable for such treatment, but not infrequently even led to operation on the stomach before a lesion existed. The practice of earlier operation however, had far reaching effects, particularly because actual facts were disclosed, resulting in more exact clinical diagnosis and a better correlation of pathology and symptoms. From a surgical standpoint, the most important result of such practice was to establish a point which I believe is not yet fully appreciated that while the effectiveness of surgical treatment of gastric cancer increases with the earlier recognition of the disease the reverse is true of the benign ulcerations of the stomach and duodenum.

The demonstration at operation of lesions of the stomach and duodenum, and the failures and successes following their surgical management, brought about a vast acquisition of knowledge related to the physiology of digestion in health and disease, of the pathological features of lesions in their various stages, of the variabilities of their clinical manifestations, and of the incidence and nature of complications. Such advances have

resulted in large part from roentgenology, for the film and screen will determine, in 95 per cent of the cases whether or not a lesion is present, will identify the situation and probably the pathological characteristics of a lesion which is present, will disclose the effects of the lesion on gastric motility, and will give most useful information as to the extent and direction of malignant invasion. Such visualization gives to the clinician opportunities impossible before such methods of examination were developed. It enables him to distinguish more accurately between the functional and organic forms of dyspepsia, and it makes possible that correlation of facts on which the structure of the therapeutics of lesions of the stomach and duodenum must be built.

Surgery of the stomach and duodenum at present, therefore, is based on a foundation of physiological knowledge that has been greatly advanced through experimental and clinical observations, exact pathological classification of lesions, accuracy of diagnosis better understanding of the indications for operation, more intelligent application of operative procedures, and established principles of technique. As a result, the surgical treatment of lesions of the stomach and duodenum now can be viewed in a broader aspect than ever before.

The urgency of establishing the safety of operation has been reflected in the gradual decrease in mortality and morbidity following operations for lesions of the stomach and duodenum, and large series of cases have been reported from various clinics of the world, in which the mortality of conservative operations for duodenal ulcer is 1 per cent or less, of gastric resection for gastric ulcer 3 or 4 per cent or less, and of resection for gastric cancer less than 10 per cent in general and less than 5 per cent in early cases. Although some of these series may be rightly considered record performances and difficult of duplication, yet they are evidence of the advances which have been made in the safety of operative procedures when there has been intelligent selection of cases and of operation, adequate preparation of the patient, and the surgeon has the required judgment, skill, and experience.

Such examples of the safety of operation on the stomach and duodenum, in respect to both mortality and morbidity should not give the impression that grave menaces are not always present in such operations. Although it is true that perfected technique has largely eliminated the dangers of serious complications directly attributable to the operations themselves, such as hemorrhage or mechanical defects in the line of suture, other postoperative sequelae equally serious may develop. By far the most important of these are postoperative pulmonary complications, which, in spite of definite progress in their prevention continue to occur about twice as frequently as they do after operations in the lower part of the abdomen. It is true that although the low mortality of operations on the stomach and duodenum belies the seriousness of pulmonary complications, study will show that at least 50 per cent of the deaths are attributable to them. Since the incidence of these complications is apparently the same whether or not the patient has been anesthetized by inhalation the primary or major factor contributing to their occurrence is often a mechanical one such as diaphragmatic spasm or unexpelled bronchial secretions. The latter are now considered as the probable precursors of the most common pulmonary complications namely bronchopneumonia and atelectasis, and the further reduction of the incidence of these complications will depend on the efficacy of methods to prevent accumulation and retention of bronchial secretions.

Now that safety of gastric surgery has reached a point from which it will be difficult to make further advances, the question of the efficacy of surgery in the cure or treatment of lesions of the stomach and duodenum becomes paramount for as W. J. Mayo pointed out the time has long since passed when the mere survival of the patient following operation for chronic disease measured the success of the operation. The relative merits of operations, as measured by ultimate results, never can be dissociated from their risk; therefore the basis on which further development will rest must take into account both the risk of operation and the possibilities of cure or palliation. It is from this standpoint that the

present status of surgery for the common lesions of the stomach and duodenum namely cancer and ulcer may be briefly discussed.

The surgical treatment of cancer of the stomach in respect to both cure and palliation should be judged not only as to the actual results of such treatment but also in relation to other methods of management of which there is none. Pessimism may be so extreme that the fact that recurrence of the disease can be prevented in a definite percentage of cases, following removal of the growth is disregarded and the fact is forgotten that nothing other than surgery offers any possibility of complete or permanent relief. Since the outlook of cure at present lies in extirpation of the growth the problem of management becomes one of recognition of the disease at a time when such treatment can be carried out. It is not to the credit of the medical profession that in only 1 out of 4 cases of cancer of the stomach, when first encountered by the surgeon can even an attempt be made to cure the patient. At the same time it would be unwise to underestimate the difficulties of early recognition for it is unfortunately true that the majority of cancers of the stomach give rise to slight or even no symptoms in their early stages. It is also true however that in the study of any series of cases in which resection is carried out the average length of time that the patient has been conscious of symptoms has been 11 months. It would seem therefore that in this lies a challenge to members of the medical profession to convince the public that slight deviations from normal are worth meticulous clinical investigation, and to convince themselves that this investigation should include the only method by which early diagnosis of cancer of the stomach can be made namely competent roentgenological examination.

Assuming that the diagnosis has been made sufficiently early the basis of management of cancer of the stomach is the surgical exploration of all malignant lesions which are apparently confined to the stomach, have not given rise to distant metastasis, and do not encroach on or involve the cardiac orifice.

The most effective treatment both in respect to maintaining low mortality and low

morbidity, and increasing curability, depends on the following factors: first pre-operative overcoming of the effects of dehydration, second, pre-operative cleansing of the stomach by lavage, third, anesthesia adequate to allow satisfactory examination of the growth and possible detection of metastasis, fourth wide removal of the growth and of a segment of the first portion of the duodenum together with as nearly complete as possible extirpation of lymph nodes, and last, such restoration of gastro-intestinal continuity that the anastomosis not only will function well, but in the event of recurrence of the disease most likely will ensure protection against obstruction of the gastro-intestinal tract.

The results of such management have shown that in various consecutive series of cases studied, in which resection has been performed for gastric cancer, the mortality can be 10 per cent or less. The patients alive and apparently well 3 years after operation average 52 per cent in those cases in which the disease was confined to the stomach and 19 per cent in those cases in which lymph nodes were involved. In the cases in which resection was performed with or without lymphatic involvement, 19 per cent of the patients are alive and apparently well at the end of 5 years.

Palliation in gastric cancer is an important function of surgical treatment. Removal of the growth has proved to be the most satisfactory procedure, because definite prolongation of life and protection against distressing symptoms frequently is accomplished. An excellent substitute for removal is complete exclusion by division of the stomach above the growth, closure of the distal segment, and uniting of the jejunum to the proximal segment of the stomach, by the method of Devine, of Melbourne. Gastro-enterostomy is usually of little benefit, and should marked or prolonged improvement follow this operation, it would constitute evidence that the growth probably could have been removed. In non-surgical management of inoperable lesions with obstruction, the value of the stomach tube as pointed out by Kussmaul in 1869, should not be forgotten. It was the practice of W. W. Mayo for many years to instruct patients in the use of the stomach tube

With this and a liquid diet of fruit juices, rice water, and so forth, he brought about much amelioration of symptoms. Radiation has been disappointing for any palliative effect.

Cancer is the most fatal organic disease of the stomach, but gastric and duodenal ulcer are the most frequent diseases. The chief problem concerning ulcers, which still awaits solution, concerns their cause. Although much contributory evidence has come from clinical and experimental investigation in relation to disturbed function, particularly secretory and motor function, and in relation to infection and to neurogenic factors, evaluation of these continues to be difficult. A lesser problem concerns the indications for and the merits of, the various operations for gastric and duodenal ulcer. Since, with the realization that it was both impractical and incorrect to attempt to classify gastric or duodenal ulcer as either a medical or a surgical disease, great progress in management came when physician, roentgenologist, and surgeon co-ordinated their opinions, viewpoints and advice. Perhaps the greatest impetus to such co-ordination can be attributed to roentgenology, which attained such perfection as to remove almost all uncertainty in determining the presence of gastric and duodenal lesions. Nevertheless, from a diagnostic standpoint there is still the pre-operative problem of determining the exact pathological character of the ulcer of the stomach. One of the most valuable advances which could be made would be some method of determining with certainty whether or not such an ulcer were malignant. It is true that the experienced clinician and roentgenologist together, by evaluating every possible sign and symptom, can be reasonably certain of the pathological character of a lesion of the stomach, but there is as yet no absolute evidence other than that which can be secured by microscopic study of the lesion after removal. Should some method become available to distinguish clinically these lesions, one from another, then ulcer of the stomach could be treated medically without the ever present fear and humiliation of attempting to cure a malignant lesion by diet and alkalis. That a gastric ulcer, primarily benign, may become malignant, is recognized

by all clinicians, roentgenologists, and pathologists the only difference of opinion is related to the frequency of this complication.

The success of the surgical treatment of both gastric and duodenal ulcer depends largely on selection of those cases for operation in which good results can be expected. This skill in selection is particularly necessary in duodenal ulcer in which variability of symptoms is much greater than in gastric ulcer. The indications for surgical treatment of gastric ulcer are relatively simple for it is a basic rule that if the ulcer fails to heal, it should be classed as a lesion other than ulcer. Even though symptoms are more or less quiescent well planned and well performed surgical operation is safer for the patient than harboring a lesion which persists. In duodenal ulcer the general indications for operations are clear when the symptoms become chronic and sufficiently severe and when such complications as impaired motility repeated hemorrhage or acute or chronic perforation have occurred. The mere presence of a duodenal ulcer is by no means a justification for operation.

The general principles of surgical management begin with the premise that the most efficient surgical treatment of gastric and duodenal ulcer is that which will accomplish the best control of the disease with the least possible risk. Consequently in ulcer the surgeon must be familiar not only with the indications for operation but also with the details of the technique of the variety of procedures in order to deal with the lesions in their various situations.

In so far as gastric ulcer is concerned, accuracy of diagnosis has made possible its recognition much earlier than formerly so that in the majority of cases the lesion is still small when operation is carried out. Furthermore, in 90 per cent of the cases the lesion is sufficiently near the angle of the stomach so that its accessibility is not a problem, and any gastritis associated with the lesion is not extensive. Such lesions lend themselves so satisfactorily to local excision, combined with gastro-enterostomy that partial gastrectomy usually seems unnecessary. The results of a well performed excision either with cautery or knife, combined with gastro-enterostomy

will equal the results of partial gastrectomy in so far as relief of symptoms is concerned moreover it has long been known that the danger of jejunal ulcer when gastro-enterostomy is done for a lesion of the stomach, is practically negligible. It is true however that from a technical standpoint alone local excision of a large lesion, combined with gastro-enterostomy may be a more formidable procedure than gastric resection. In the high-lying large lesions, even radical operation may be unwise, for not only does the sacrifice of healthy stomach seem unreasonable but re-establishing gastro-intestinal continuity is fraught with much added danger. In such cases when the lesion is so situated that direct attack on the ulcer is not advisable healing can be brought about in a certain percentage of the cases by either gastro-enterostomy or jejunostomy.

In the treatment of duodenal ulcer there is much discussion as to the relative merits of operations, but it should be realized that no surgeon regardless of what operation he may favor applies it in all cases. It is true also that the greater the experience of the surgeon, the more skilled he is in selecting the procedure which will best meet the requirements in each case. The indications for the various procedures, therefore, present a very complicated question, since the age, sex, physical condition, and even the personality of the patient, as well as the variability of the lesion the known physiological effect of the operation, and the skill of the surgeon must all be taken into consideration. The basis on which the most common operations for duodenal ulcer are carried out can be briefly formulated. The more chronic the lesion and the more motility has been impaired the clearer is the indication for gastro-enterostomy. On the other hand as Ryle pointed out, no attempt should be made to circumvent mechanically a lesion which is producing no considerable mechanical disturbance of function. Again the older the patient (which usually implies relatively lower gastric acidity) the more clearly is gastro-enterostomy the operation of choice. The contra indications to gastro-enterostomy are the indications for those procedures which include removal of the lesion of the duodenum

and reconstruction of the outlet of the stomach. The many variations in such direct methods are designed for these purposes, first, to remove as thoroughly as possible the lesion or lesions of the duodenum, second to provide a satisfactory outlet for the stomach. Partial gastrectomy for duodenal ulcer should, I believe be reserved for those patients who have had such serious bleeding that thorough removal of the first segment of the duodenum is distinctly to their advantage, and for those patients who are suspected of suffering from a high liability to recurrent ulcer. The most important of all the indications for gastric resection for duodenal ulcer should be that the operation can be done with little more risk than a conservative procedure. It should be remembered, in this connection that no operation can entirely insure the patient permanently against recurrence.

When surgical treatment is carried out on the basis outlined the results will show that in cases of chronic duodenal ulcer in which surgery is clearly indicated, approximately 90 per cent of the patients can be given complete and permanent relief of symptoms and protection against recurrence of the disease. This is a great accomplishment in a disease which has as chronic characteristics as has duodenal ulcer. In a recent article Walton in reviewing his experience in more than 1800 operations for chronic ulcer emphasized the excellent results which can be obtained in duodenal ulcer by use of conservative procedures, one of the most important reasons why such results can be reported is that not only was skill employed in determining the indications for

surgery but also good judgment was used in selection of the operation.

Gastric and duodenal surgery is not static, and to be progressive surgeons must persistently adjust themselves to the clinical variabilities of the diseases of the stomach and duodenum to changing viewpoints as to causes of such lesions to the difficulties of instituting surgical intervention at the optimal time to new or revised methods of treatment, both surgical and medical, to shifting concepts of physiology particularly as it applies to restoration of function following various operations and to the inherent technical problems. The stomach and the first portion of the duodenum are particularly vulnerable to those conditions which may be precursors of chronic disease. One reason for this is that the stomach and first portion of the duodenum which are derived from the foregut are of later development in embryonic life than is the remainder of the small intestine and the colon and consequently have not acquired maximal immunity. Another reason is that the stomach, since it is insensitive to irritants which in other parts of the body would arouse painful stimuli is subjected to injury and abuse. This may explain the frequency of lesions of the stomach and duodenum particularly the frequency of cancer among men. It is such problems as these that have made the developments in the surgery of such a complex field one of the epochs of medical history, and further advances in the surgical treatment of diseases of the stomach and duodenum will always demand adherence to the same precepts and practices as characterized so notably the life of John B. Murphy.

INFECTION IN CLEAN OPERATIVE WOUNDS

A NINE YEAR STUDY¹

FRANK L. MELENEY M.D. F.A.C.S., NEW YORK, NEW YORK

MANY of the details of the sterile technique of surgical operating rooms have been passed on to us by hospital tradition or by word of mouth from our immediate predecessors on the staff. Most of these details we have taken for granted without questioning their rationale. We assume that at some time in the past the reason for this or that step in our procedure was adequately demonstrated. Certain methods are common to all good hospitals. Others have been instituted locally but are not used elsewhere. It is only on such occasions as this when surgeons gather together to discuss their problems and to see how the other fellow does it, that we find certain steps in the sterile technique which are different from our own. Then if we are interested we question our hosts, or our confrères or ourselves, in an effort to determine which methods are better theirs or ours. When we ask for proof that a certain step is better we often find that the other fellow has always done it that way but doesn't know why. Consequently we do not make this change in our own technique. Or worthy changes appear too costly in time or money to warrant their adoption. Often we wait for a catastrophe such as a fatality or a series of deaths or an epidemic in our own hospital to call us to account for our methods. Such an event may disturb our equanimity for a short time and then be forgotten or it may irritate us to the point of making certain changes, or it may stimulate us to re-survey the whole problem and rationalize the whole procedure, weeding out useless steps and adding methods of proved worth in order to bar the way to a future occurrence of the same tragedy. But so often the experience of one individual or one group cannot be passed on to another individual or group. One may be able to profit by his own mistakes but not by those of others or learn from others' experiences.

I must confess that we were going blissfully on our way using operating room technique

handed down for several decades in the firm conviction that it could not be improved upon and that we were getting excellent results in our wound healing. One day on staff rounds in the spring of 1925 a clean case was found to have a wound infection. The matter came up for general discussion and the chief of one of the surgical services was asked what percentage of clean wounds he thought became infected. He was an individual extremely careful to be honest and straightforward in his statements. He replied that he thought, if every minor infection were counted, the total might possibly reach 2 per cent. I stated my impression that we were then having more infections than usual and that they might then be in the neighborhood of 5 per cent. I was thereupon assigned the task of finding out what the actual figures were. The records were reviewed from the beginning of 1925. All of the clean cases were listed together with all of the circumstances of the operation. The dressing notes were scrutinized and any evidence of infection during the process of wound healing was noted.

It soon became evident that not 2 per cent or 5 per cent but about 15 per cent of our clean wounds were becoming infected and that a large number of the serious infections were due to the hemolytic streptococcus. The actual figures were seven and a half times as great as had been suspected by an honest observer. This fact is emphasized because I am sure that impressions are woefully inaccurate in most instances and when you hear any one say that the wound infections in his hospital are negligible, the statement should be discounted unless there is an actual count and a careful study of the dressing notes. Operators who permit the internes to remove the stitches from their wounds may never know how many of the cases become infected. They have a false sense of security and yet they may conscientiously say that they seldom if ever see a clean wound become infected.

From the Surgical Service of the Presbyterian Hospital and the Bacteriological Research Laboratory of the Department of Surgery, College of Physicians & Surgeons, Columbia University. Presented at the symposium on the "Treatment of Infections" before the Clinical Congress of the American College of Surgeons, Boston, October 17-20, 1924.

Some years ago Brewer shocked the attending staff of a New York hospital when he studied wound infection and found that 30 per cent of the clean cases became infected. By rigid attention to the possible sources of infection this figure was immediately reduced in his hospital.

When we found to our dismay that many of our clean wounds were developing infection we decided to try to discover where the organisms came from and how they gained a foothold in the tissues.

THE SOURCE OF THE INFECTING ORGANISMS

The organisms which were cultured from the wounds gave a clue to the sources of contamination. Yellow and white staphylococci were found in the majority of cases. A much smaller number yielded hemolytic streptococci or non hemolytic streptococci. More rarely *Bacillus coli*, *Bacillus subtilis*, *Bacillus pyocyaneus*, *Bacillus proteus* and diphtheroids were found. The variety of the organisms suggested that the source of these organisms might be various. Every step of the sterile technique was carefully scrutinized to determine if possible, where the bacteria came from. It was thought, first of all, that they might come from the materials entering the wound for example, the gauze sponges supposedly sterilized by autoclaving. (Two years ago Dandy maintained that almost every wound infection resulted from contamination from this source and stated that in his institution infections had completely disappeared following the prolongation of the sterilizing process.) Or it was thought that the germs might come from the instruments supposedly sterilized by boiling, or the knife blades and sharp instruments supposedly sterilized by soaking in alcohol, or from the catgut supposedly sterilized by heating or from the water or saline used during the operation supposedly sterilized in large tanks. Second it was thought that they might come from the dust particles in the air which dropped upon the sterile field during the course of the operation. Third they might come from the skin of the patient supposedly sterilized by the skin antiseptic, or from the deep tissues or from the blood of the patient. Fourth, they might come from the nose or throat of the

operator or his assistants supposedly masked. Fifth, they might come from the hands of the operators supposedly sterilized by the process of scrubbing with soap and water and soaking in antiseptics before putting on gown or glove.

Our chief and immediate concern was to find the source of the hemolytic streptococci which caused serious infections in 8 clean cases during the first 5 months of 1925. We cultured every kind of material which had been prepared for the sterile field—those which had been boiled, those which had been autoclaved, those which had been soaked in antiseptic—but found no trace of the hemolytic streptococcus. The sterile water tanks occasionally contained gram negative organisms but never a hemolytic streptococcus. The exposure of blood agar plates to the air of the operating rooms for several hours on many occasions yielded only one colony of hemolytic streptococcus. Cultures from the skin of the patient seldom gave this organism. It was only when we came to examine the hands and the noses and throats of the operating personnel that we found a field of activity for the hemolytic streptococcus. Much to our surprise 33 per cent of the operating room staff harbored this organism in the throat and many individuals carried it in the nose as well. This organism could also be recovered occasionally from the hands of the doctors. It was evidently picked up from the dressings and bedclothes of patients suffering from hemolytic streptococci lesions and may have been transferred by the doctor to his mouth. Cultures from the hands of the doctors just before dressing these cases seldom yielded these bacteria but directly afterward they were almost invariably present.

The nose and throat as sources for infecting bacteria. The above findings suggested the direction for our immediate researches. A survey of noses and throats of the entire operating personnel was made. Fortunately (and I use the word advisedly for I realize how lucky we were), just at that stage of our study a clean hernia developed a hemolytic streptococcus wound infection. When we looked up the record we found that 3 members of the operating team were carriers of the hemolytic streptococcus. It had been cultured from the throats of 2 of the doctors and from the nose

as well as throat of the instrument nurse, just a few days before the operation. By a strange coincidence also as it proved cultures of the patient's nose and throat yielded hemolytic streptococci. The question arose which of the extraneous strains matched the organism which had been recovered from the wound. By the injection of rabbits with the several strains, agglutinating sera were obtained and then by agglutination and cross absorption of agglutinin tests, it was indisputably shown that the organism from the wound was identical with the organisms from the nose and throat of the instrument nurse and entirely different from the strains from the patient's nose and throat and the strains from the 2 doctors. The evidence was overwhelming that the organism had been discharged from the unmasked nose or throat of the instrument nurse upon the sterile field. Thereupon the order went forth for all operating teams with out exception to mask both nose and mouth with fine meshed 4 ply gauze masks. This measure, we found, reduced the number of organisms deposited upon a blood agar plate held in front of a person so masked to approximately the number deposited on a control plate some distance away. This complete masking was later extended to all persons both sterile and unsterile entering the operating room except the patient himself. Thereupon our hemolytic streptococcus wound infections were immediately reduced to casual numbers that could probably be accounted for by contamination from other sources.

Reports of this demonstration appeared in the literature (8, 9) and individuals here and there profited by our experience but the matter has not received general recognition although Dr Staige Davis has recently called attention to it again. I have since seen, and you will see here in Boston as well as in Chicago, Philadelphia, Baltimore and in my own home town of New York, surgeons who do not mask the nose and who do not know that they are subjecting their patients to an unjustifiable risk from the neglect of this one measure in sterile technique.

Dr Walker of this city was stimulated by a similar misfortune in his own hospital to study the problem of adequate masking and demon-

strated that the only germ-proof mask was one containing an impermeable membrane such as rubber. Its advantage over the 4 ply fine meshed gauze mask is apparent to any one who will take the trouble to blow smoke through these two masks, but the impermeable mask is far from ideal because of its discomfort and the other mask seems to be satisfactory for all practical purposes, for it will stop droplet contamination from both nose and mouth. The anesthetists objected to masking because they said it was difficult to breathe when the fumes of the anesthetic were added to the annoyance of the masks, but when they were exempt for a few months 3 cases of hemolytic streptococcus infection developed following thyroid operations and the proximity of the unmasked anesthetist in these operations rendered them suspicious sources of these organisms. Now there are no exceptions and if any member of the staff is known to have a cold he is either relieved from operating room duty or is required to wear two masks and to double the time for scrubbing and antisepticing his hands before operation.

We realized of course that the noses and throats of the operating personnel were not the only source of the organisms causing wound infections but this was the most significant finding in our first year's study and the statistics obtained for 1925 served as a basis upon which to measure any improvements in our sterile technique. The 1925 results proved to be of such interest and importance to the staff that it was decided to make it continuous. This has kept every member of the staff alert and "infection conscious" and has made us all strive continuously to improve our record.

The autoclaved materials as a source of organisms. We have maintained a continuous check on our autoclaves by inserting in the center of the material a cotton thread saturated with *Bacillus subtilis* spores and then testing for their destruction. In 1929 we changed the test organism to another strain and soon afterward began to obtain occasionally positive cultures. No change had been made in the sterilization process but we found that our new test organism would stand boiling for 15 min

notes. Rather than to change back to a more susceptible test organism we decided to find a way of killing this resistant strain. Our sterilizing time had been 30 minutes at 18 pounds pressure preceded by an evacuation of the air just sufficient to reach minus 10 for a few seconds. With this amount of air evacuation we found that it took 1½ hours to consistently kill our test organism in the center of the central drum, and this period of sterilization frequently scorched the materials and softened the gloves. By prolonging the evacuation time at minus 10 to 15 minutes however a sterilization time of 30 to 45 minutes was sufficient to kill the spores. Since that time we have followed this procedure and our tests have consistently yielded no growth. But, although Dandy claimed that the autoclaved materials are the sole source of organisms causing wound infections this change in our own technique has not stopped our wound infections.

Boiled instruments as a source of infecting organisms The boiling process for sterilizing instruments has proved to be effective in all of our tests and conscientious timekeepers who will wait for the full 5 or 10 minutes should have no fear of presenting unsterile instruments to the operating table. The chief danger from this source occurs when an instrument which has been forgotten or one which has been called for in a hurry is rushed through in less than the minimum time. To be sure, some heat resistant spores will withstand boiling for 5 minutes but so far as I can ascertain the only species which may do so are non-pathogenic, such as *Bacillus sporogenes* and *Bacillus subtilis*.

Instruments "sterilized" in antiseptics as a source of infecting organisms The sterilization of sharp instruments such as knife blades, scissors and needles as well as syringes, but tons, silk worm gut and catgut tubes has been a real problem. The odor from the apparatus and one fire made us give up the oil sterilization process advocated by Lahey and others. He found that soaking for 15 minutes in 50-70 per cent alcohol (our former method) was entirely inadequate to destroy even the commonest organisms. We experimented with various antiseptics by contaminating knife

blades with heavy suspensions of mixed bacteria and subjecting them to contact with these antiseptics for varying lengths of time. We found that the best antiseptic to sterilize and at the same time maintain sharpness was the Bard Parker germicide. We used that for over a year but finally had to yield to the protests of the nurses who handled those materials because severe burns of the skin resulted from contact with this germicide or its fumes. Furthermore, a number of severe reactions following spinal anesthesia, with central nervous system symptoms and increased cell count in the spinal fluid, were attributed to a small amount of this chemical having remained in the needle or syringe at the time of lumbar puncture. Occasionally also we produced skin necrosis with local anesthetics and the germicide was blamed. Now these instruments are either boiled or soaked in pure carbolic acid for 15 minutes. The Bard Parker germicide is still being used for the sterilization of the catgut tubes which contain the non-bollable variety of gut.

Catgut as a source of infecting organisms Catgut has often been blamed for wound infections and there is no doubt that it has been responsible for certain of the cases due to anaerobic spore-forming organisms such as the tetanus bacillus and the gas gangrene group of bacteria. These were more common a generation ago than they are now. Welch once said that these wound infections constituted one of the chief reasons why Halsted substituted silk for catgut as suture and ligature material (15). This point will be mentioned in more detail below. In 1923 before this study began 2 postoperative infections due to *Vibrio septique* in the Presbyterian Hospital were directly traced to inadequately sterilized catgut. The catgut firm was made liable in a court of law. In 1927, while this study was in progress the author was asked to see a patient with a postoperative wound infection in another hospital. The contamination was traced unmistakably to inadequately sterilized catgut sold by another firm. Death occurred in this case and in 4 other similar cases (10). This led to a study of the methods of catgut manufacture and its sterilization as well as tests for its sterility. Several of the catgut

firms followed this study closely and modified their methods according to its findings (11). A standard method of testing for sterility was developed (12). This has been accepted and is now said to be employed by most of the catgut firms. Unfortunately neither the American College of Surgeons nor the American Medical Association has been willing or financially able to set up a laboratory control for determining by periodic tests of specimens of catgut purchased on the open market whether or not the products now sold are measuring up to the standard of sterility. But the test for catgut sterility is one which can be carried out by any laboratory equipped for anaerobic bacteriology and until either the government or some medical organization undertakes to control these products, the proposed tests should be made in a reliable laboratory before any particular brand of catgut is adopted by any surgical clinic. Although improperly sterilized catgut may at times contain the organisms of tetanus or gas gangrene it probably very rarely contains non spore forming heat susceptible organisms like staphylococcus and streptococcus, which are the commonest organisms of operative wound infections. However as shall be seen presently the use of catgut in surgery may and almost certainly does favor the growth of organisms introduced at the time of operation.

Contamination from the hands of operators. We have stated above that doctors and nurses frequently contaminate their hands with purulent discharges from the wounds of patients when changing their dressings or handling their bedclothes. (If gloves are used at the time of dressings such contamination is minimized.) If the doctor or nurse then proceeds to the operating room the possibility of carrying those organisms to the sterile field is a very real one. The scrub-up is the intervening barrier. In almost every hospital the surgeons scrub their hands with soap and water for a variable length of time. In this procedure the time is not as important as the vigor with which the superficial layers of skin and the crevices and grooves are scrubbed. Countless organisms are removed in this process. The after treatment of hands then varies considerably in different clinics. Some use alcohol others

bichloride, biniodide, lime and soda, iodine, or a combination of these. The antiseptic effect of these chemicals depends upon their close contact with the bacteria and the duration of this contact. Our present technique calls for a 5 minute scrub-up with green soap in running water and 5 minutes by the clock in lime and soda, followed by 70 per cent alcohol. For those whose skin is irritated by the lime and soda, the time may be abbreviated but the nails must receive a generous supply and be cleaned with the antiseptic. The full time of 10 minutes must then be completed in the alcohol. Cultures from the hands and nails following this treatment rarely show organisms. Lime and soda seems to be particularly effective and the odor of chlorine may frequently be detected under the nails several hours after the operation is over. There is a tendency on the part of certain surgeons at times to shorten the various steps in the scrub-up and I am convinced that when this is done organisms are carried over to the sterile field. An added safeguard lies in having the sterile nurse hold the glove open so that the hand may be inserted without touching the outside. If gloves are broken or pricked during the operation, good practice demands a change at once because the hands, even if sterile at the beginning of the operation may be contaminated by skin organisms discharged from hair follicles or sweat glands later on. The method of using wet gloves makes it impossible to prevent contamination of the outside of the glove with organisms still present on the hands.

Contamination from the skin of the patient. In the earlier years of our study there was an urgent demand for a skin antiseptic to replace the time honored iodine which has been criticized because it occasionally produces burns and does not effect real sterilization of the skin. Picric acid acriflavine gentian violet mercurochrome various other dyes and combination of dyes, hexylresorcinol, metaphen and merthiolate have all been recommended by enthusiastic advocates and statistics have been presented to prove their worth, but the results that we have obtained in experimental animals have not consistently indicated the superiority of any skin antiseptic over the others. We at

tempted to compare iodine with mercuriochrome-acetone alcohol which was said to have extraordinary penetrating qualities. At the beginning of a hernia operation, 5 minutes or more after the antiseptic had been applied a bit of skin from the region of the pubic hairs was cut out with freshly boiled instruments and transferred at once to cultures medium. Of ten cases prepared with iodine 9 yielded growth of staphylococci, *Bacillus subtilis* or diphtheroid bacilli, 2 of these wounds developed trivial infections. Of 10 cases prepared with mercuriochrome 8 showed growth. One of these yielded *Bacillus coli*, *Bacillus welchii* and staphylococci and developed a serious infection. "Not much to choose" you will say, "between the two both being inadequate skin sterilizers." That is true and we have repeatedly carried out this same test in animals with the other antiseptics. After contaminating the skin of rabbits with mixed cultures of common organisms—such as *Bacillus coli*, *Bacillus subtilis*, *Bacillus welchii*, staphylococci and streptococci we have applied the antiseptics for varying lengths of time and then snipped out bits of skin for culture. No antiseptic yet proposed has shown any superiority over iodine.¹ If the organisms in the deep glands and ducts of the skin cannot be destroyed by any antiseptic yet found, the knife which passes through these ducts and glands must contaminate the wound with the organisms contained therein. This might be avoided by using the electric 'cutting current' or by employing a knife blade soaked in carbolic acid. However the injury to the tissues from cautery or antiseptic might offset the advantage gained. If a knife is used it may be discarded when the skin has been incised. Greater contamination of the wound may take place during the course of the operation if the neighboring skin surfaces are exposed, for the skin secretions almost certainly wash out bacteria from the ducts during the course of an hour and these reaching the surface may be wiped into the wound unless the skin edges are protected. This may be done most effectively by attaching towels to the skin margin with Michel clips.

The bacteria contained in the deep ducts and glands may again become of some importance during the skin sew up. If a continuous suture is used the needle may pick up organisms and distribute them all along the suture line. This source of contamination may be minimized by using individual interrupted stitches on separate needles as Halsted advised.

Contamination of the wound from air organisms. Lister believed that organisms dropping from the air played an important rôle in wound infection and developed his elaborate apparatus for spraying the atmosphere. It later developed that this was one of the relatively minor factors. However with the other sources greatly reduced or eliminated if nothing is done to minimize contamination from this source it becomes relatively important again. If a blood agar plate is exposed to the air of an operating room for an hour and then incubated, its surface will be more or less thickly covered with dust particles and beneath some of these particles colonies of bacteria of various kinds develop. Staphylococci will make up the majority of these colonies. Yellow and white, hemolytic and non hemolytic will all be represented. *Bacillus subtilis*, *Bacillus coli*, non hemolytic streptococci and diphtheroid bacilli will be present in smaller numbers. Hemolytic streptococci will appear rarely. Yeasts and moulds are relatively common. The number of colonies will depend upon a number of factors. In the old hospital one operating room was on the ground floor and a second on the floor above. Cultures from the ground floor operating room were consistently more numerous than those from the upper floor and yielded roughly two colonies for every minute of exposure. In the new hospital, with the operating rooms on the sixteenth floor, the colonies were found to be just half as numerous as they were in the old hospital, namely, one colony per minute of exposure. The fresh air supplied to these rooms is filtered. But this filtration is nullified by the opening of doors, the occasional coming and going of assistants, the spread of blankets and the general movement of the people connected with the operation. If plates are exposed in one of these rooms when no operation is going on and no

¹ Emphasis should be made of the importance of a careful preliminary gauze swabbing of the field with alcohol and then either or other alone before applying the iodine.

one moving in or out the number of colonies appearing on the plates is just one tenth of that developing on plates in a room where there is activity during an operation. In these rooms visitors are required to observe the operations from a balcony protected by plate glass. If visitors are permitted to come on the floor of the operating room as is the case in many places, it is obvious that the number of air organisms are materially increased, especially when the visitors are not properly masked.

The area of a blood agar plate is approximately 7 square inches. The sterile field in cluding the operating table and instrument tables might vary from 4,000 to 7,000 square inches. It would seem fair to assume, therefore that in a busy operating room in the course of an hour from 35,000 to 60,000 bacteria fall upon the sterile field. It is obvious that these figures may be materially reduced by minimizing the activity within the room and the opening and closing of doors, by removing objects which collect dust, and by refusing admittance to unnecessary persons.

Canopies over instrument tables cut down air contamination. Street shoes should be covered. Walls and floors should be frequently washed with germicides. Constant filtration of the air might be of considerable value, where dust is prevalent.

FACTORS WHICH FAVOR THE DEVELOPMENT OF WOUND INFECTION

The factor of local tissue susceptibility. During the first 5 years of our study our chief efforts in our attempts to reduce the number of our infections, lay in considering ways and means of reducing the sources of contamination. It is obvious that every wound becomes contaminated at the time of operation but fortunately relatively few become infected. One reason for this, which we assume but cannot prove, is that individual patients may vary in their susceptibility to infection. It is almost self-evident also that trauma and rough handling of tissues decrease the local resistance to infection. Extravasation of blood the use of drains mass ligation of tissues and the tension upon or strangulation of tissues by sutures or retention stitches as well as the mechanical factors of motion (as in certain wounds of the face neck, and extremities) or distention from within (as in abdominal wounds) play a rôle by breaking up the fine fibrous network of the early stages of repair or by cutting down the blood supply.

The factor of suture material. During the first 5 years of our study it was evident that certain types of operation regularly had a higher incidence of infection than others. Radical mastectomy partial thyroidectomy recurrent hernia, ventral hernia, open reduction of fractures headed the list. There seemed

to be a reason for this in the nature of the operation except in the case of partial thyroidectomy. Practically all of the thyroid operations were being done by the two surgeons associated with the thyroid clinic and it did not seem possible for them to reduce their high incidence of hematoma and infections. In the summer of 1929, while one of the thyroid surgeons was on his vacation the author had the opportunity of performing 5 thyroid operations in close succession. As had been his habit since his experience in thyroid surgery in Peking China, under the leadership of Dr. Adrian S. Taylor, a former pupil of Dr. Halsted, the author used fine silk entirely for ligature and suture material in these cases. The differences in the healing of these wounds compared with the catgut sutured wounds was obvious to all who saw them. The second thyroid surgeon observed these results and was persuaded to

try silk. He performed 10 consecutive cases with silk, all of which healed promptly and kindly without trace of hematoma or infection. He then sutured 10 cases with catgut and obtained 4 hematomata and 2 infections. He was convinced of the superiority of silk and determined to use it entirely thereafter. Some months later the other thyroid surgeon was also persuaded to make the change. The results which were obtained were most surprising and most convincing. These are shown in Table I. When the report of the year 1930 was presented to the staff it was suggested that the use of silk be extended further particularly to those cases which were yielding such a high percentage of infection, namely open reduction of fractures, recurrent hernias and radical mastectomies. The fracture service surgeons decided to use it for all of their clean cases and a certain group of the general

Fig. 1. Silk and catgut sutures comparisons.

surgeons agreed to use it on all hernias. In the next year's report an opportunity was given to compare silk and catgut in these 2 large groups. Again the superiority of silk was demonstrated unmistakably as Table II shows clearly. In the last 2 years silk has been substituted more and more for catgut. In 1932 we were able to compare silk and catgut in 3 large groups (see Table III). In 1933 a large majority of all clean wounds were sutured with silk. For the first time we were able to compare all of the cases closed with silk with all of the cases closed with catgut (see Table IV). The results amply confirm the early reports and we have come to feel that this one modification in our technique has been more important than any other in reducing our wound infections. In 1933 the 2 thyroid surgeons experimented with linen as a substitute for silk but their results were unsatisfactory as Table IV so clearly shows.

As we have said above Halsted, following the lead of Kocher in Bern, substituted silk for catgut in suturing clean cases partly because of the uncertainty of catgut sterilization in those days, and partly because he noticed that the wounds healed "more kindly" even when there was no infection. There was less redness, swelling and induration. Thus he became the chief advocate of the use of silk in this country and his pupils have almost all followed his example and spread this gospel abroad. On the other hand few surgeons who did not come under his influence either directly or through his followers and pupils have been convinced that he was eminently right in his

conviction nor have they been willing to change their technique in this respect.

It seems strange that Halsted did not attempt to prove his point either by well controlled clinical or careful laboratory experiments. He was sure of his ground on the basis of his own experience and his own observations. In 1925 B. H. Goff made a study of wound infections in clean cases and presented fairly good evidence that wounds sutured with silk were less likely to become infected than when other materials were used. Our results amply confirm the impression which he obtained from his study. During the past year Vivier, one of the senior fellows in our surgical department, at the suggestion and under the supervision of the director of the service, has added clean-cut evidence from a series of animal experiments, which strongly supports the view that silk is superior to catgut. With rigid operating room technique he produced two wounds extending through the wall of the abdomen in a large series of rabbits. One side was sutured in layers with finest silk and the other with the finest catgut. Each side was operated on with completely separate sterile set ups and took the same length of time. One animal in the series was sacrificed each day for 10 days. Cultures were made from these wounds in a dust proof chamber and by taking approximately 1 cubic centimeter of tissue from each side an effort was made to estimate the number of viable bacteria actually present on its surface by shaking the tissue in 5 cubic centimeters of broth and diluting this down through a series of 1 to 5 dilutions.

TABLE VII—DAYS IN HOSPITAL AFTER OPERATION—AVERAGE 5 YEARS

Clean	12.4 days
Infected	23.3 days
Hæmatoma	10.1 days

In practically every case the catgut wounds contained more bacteria than the silk wounds as Figure 1 shows. Microscopic sections showed that the cellular and fluid exudation around the strands of catgut was infinitely greater in amount than around the silk. Therefore we now have both clinical and experimental evidence of the superiority of silk (Fig. 1).

We believe that the superiority of fine silk over catgut is due to the following facts. First of all hæmostasis is better, for the silk knots do not become untied as easily as catgut knots, particularly when the wound surfaces move more or less constantly as in the thyroid operation. Second, the cellular and fluid reaction about silk is minimal while the reaction about catgut is maximal. Silk is almost inert in the tissues. Catgut is dead tissue which must be digested. In the third place the use of silk automatically requires the surgeon to be more gentle with the tissues. His sutures and ligatures are less likely to be pulled tightly enough to strangle tissue. This often happens when catgut is used and increases with the postoperative cedema. For these reasons, with a certain inevitable amount of bacterial contamination, infection is more apt to develop in tissue in which catgut has been used than where silk has been employed. Halsted observed, and our statistics as well as our tissue sections prove, that wounds sutured with both silk and catgut are more apt to

Fig. 2 Seasonal incidence of wound infection composite curve of 9 years.

become infected than when either is used alone. This is probably due to the fact that in a wound in which organisms are able to gain a foothold easily, silk acts as a foreign body which must be extruded. For the same reason silk should not be used in clinics or by operators who are not willing to strain every effort to minimize contamination by all of the methods mentioned above which have been devised for that purpose or by those who are not willing to minimize trauma to the tissues or tension of the tissues during the operation or by those who are not willing to take the time to obtain perfect hæmostasis, or by those who are not willing to mask adequately both nose and mouth. My chief Dr. Allen Whipple, emphasized these points in an admirable review of the subject which appeared last year in the *Annals of Surgery* and I desire to reiterate them emphatically here. However, I am willing to predict with confidence that any surgeon who will perfect his technique in these respects will be able to obtain "kindlier" wound healing with fine silk than he is now obtaining with catgut with or without those refinements of technique.

The rôle of drains and hæmatomata. During 7 of the last 9 years we have studied the rôle of drains in the production of infections. In every year but one, a larger per cent of infections developed in the drained cases than in the undrained and the average per cent of infections in drained cases greatly exceeded that in

TABLE VIII—WOUND INFECTION 9 YEARS

Year	Total	Cases	Per cent	Serious	Per cent	Trivial	Per cent	Total Inf	Per cent	Healed	Per cent

033	31	976	95	3		41	56	54	48	63	55

the undrained cases, but we cannot be sure whether this was due to the drains or to the condition which seemed to the surgeon to require drainage (Table V). There is no question, however, about the rôle of hematomata. Wounds which develop collections of blood or serum are unquestionably more prone to become infected either because of organisms introduced during the operation or later during dressings. Our studies have seemed to show that wounds may become infected following secondary contamination at the time of dressings as well as primarily from contamination introduced at the time of operation. This applies chiefly to wounds which develop hematoma or necrosis of skin from excessive tension. In a few cases each year there has been a good excuse for the development of an infection independent of the operating room technique. These points are brought out in Table VI.

PROLONGED HOSPITALIZATION OF INFECTIONS

It seems important for surgeons as well as hospital superintendents to know that patients with clean wounds which become infected have to stay in the hospital about twice as long as they would if their wounds had remained clean. This fact is shown in Table VII.

ANNUAL RESULTS FOR NINE YEARS

During the past 9 years we have gradually modified our operating room sterile technique to conform with the facts which we have presented above and we have gradually reduced our infections to a third of the former figure, as Table VIII shows. Time will tell whether

or not we have reached the irreducible minimum.

The composite curve showing the seasonal incidence of wound infection is shown in Figure 2. It does not show the spring peak which appeared in Dr. Walker's curve and in our own (7) when hemolytic streptococcus was prevalent before the period of adequate masking.

SUMMARY

1. We have carefully studied the question of the infection of clean operative wounds and have shown that general impressions of the incidence of wound infection is erroneous unless backed up by carefully prepared statistics.

2. We have considered the possible sources of contamination and we believe that the important origins are (a) the nose and throat of the operating personnel (b) the hands of the operating personnel (c) the skin of the patient (d) the air of the operating room and (e) the instruments and materials used in the operation.

3. We have suggested ways and means of minimizing contamination from all of these sources, placing particular emphasis on efficient autoclaving and the proper masking of the nose and mouth of the operating personnel.

4. We have considered also the factors in the wound itself which favor the development of an infection. Laying particular stress upon the advantages of fine silk over catgut as ligature and suture material. We have stressed the necessity for perfecting all of the steps in sterile operative technique if fine silk is to be used successfully.

5. We have shown a steady improvement in avoiding wound infection following the

gradual modification of our technique based upon results of our study

6 The study has been of interest to every member of the staff. It has rendered him "infection conscious" and stimulated his efforts to reduce further the incidence of wound infection.

7 Theoretically, there is an irreducible minimum in the incidence of wound infections. We do not claim to have arrived at that point

Discussion

DR. IRVING J. WALKER, Boston. With the short period of time allotted for the discussion of Dr. Meleney's interesting paper, I shall consider only one aspect of the infections of clean surgical wounds, namely that of the so called epidemic hemolytic streptococcus infection occasionally occurring on surgical services.

The late Dr. Arthur T. Cabot, surgeon to the Massachusetts General Hospital once made the statement that every surgical operation was an experiment in bacteriology. If one accepts the fact that all surgical wounds, the clean as well as the infected are accompanied by bacteria from an extrinsic source, then one can appreciate the wisdom of the above statement. Fortunately in the case of the clean surgical wound these bacteria are usually not pathogenic and therefore cause no harm.

When, however, there chances to be a strain of pyogenic organisms of considerable virulence and as a contributory factor a lowered resistance on the part of the individual, an infection of the wound may result, with its morbidity and possible mortality.

It so happens that we have had the opportunity to observe 4 epidemics of hemolytic streptococcus infection, 3 on surgical services and 1 on an obstetrical service in Massachusetts hospitals. In 2 of these—both surgical—we were able to study the epidemic somewhat carefully.

We have considered as an epidemic of wound infections due to the hemolytic streptococcus a situation where there were 3 or more infections of clean surgical wounds due to the above mentioned organisms occurring on a service simultaneously or at near intervals. As a result of observations and a study of masks, we have made the following findings which may be of some value in the prevention of hemolytic streptococcus wound infections of the epidemic nature.

1. In the 4 epidemics cultures from the hands, sterile goods, instruments, solutions, etc., showed no evidence of the hemolytic streptococcus.

2. Study of the masking situation showed that masking was inefficient in the 4 epidemics.

3. All 4 epidemics of sepsis occurred during epidemics of respiratory disease.

4. Three out of the 4 epidemics of infection occurred during the winter months when epidemic respiratory disease is most prevalent in this part of the United States.

5. In the 2 epidemics, both surgical, more carefully studied, the percentage of streptococcus carriers in the operating room personnel including the surgeons, was 50 per cent and 58 per cent respectively.

Among those patients with clean wounds which became infected with the hemolytic streptococcus, the percentage of those having hemolytic strepto-

cocci in the nasopharynx in the 2 epidemics studied was 55 per cent and 31 per cent respectively. In fairness it should be stated that all bacteriological studies in these 2 epidemics were made after the sepsis was discovered.

6. A study of masks submitted from 60 hospitals in the United States showed that none could be considered efficient from the point of view of preventing the passage of organisms through the material under all the conditions for which a mask might be called upon for service and that the variables in the efficiency of the masking situation were as follows: (a) whether or not the nose as well as the mouth was covered (b) materials used in the mask (c) thickness of the material (d) duration of the operation (e) whether or not the mask became moist (f) the amount of conversation carried on by those masked.

7. We concluded that the ideal surgical mask should be one that—(a) under all conditions will absolutely prevent the passage of organisms through the material of the mask in the direction of the wound or material concerned with the operation when both the nose and the mouth are covered (b) will be comfortable in all degrees of temperature

and will not fog glasses (c) will be of low original cost or of such construction that it can be used economically many times with sterilization following each use. (We might state in passing that we have not found the ideal surgical mask.)

8. Theoretically if all other aspects of aseptic technique can be assured epidemics of hemolytic streptococcus wound infection can probably be prevented by eliminating from the operating room all who are streptococcus carriers. This seems not to be feasible because of the rapidly changing bacteriology of the nasopharynx. The danger of such epidemics can be lessened by forbidding any individual who has the slightest inkling of an upper respiratory tract infection to enter the operating room. A practical procedure to minimize such infections should be the use of a mask during epidemics of respiratory disease and during the winter months, the materials of these masks to be impervious to currents of air, even though they are not as comfortable as could be desired.

We offer for further intensive study the query as to the likelihood of hemolytic streptococcus carriers among surgical patients infecting their own wounds by the hematogenous route from a focal infection.

INFECTIONS OF THE LIP AND FACE¹

FREDERICK A. COLLIER, M.D., F.A.C.S., AND LUIS YGLESIAS, M.D. ANN ARBOR, MICHIGAN
From the Department of Surgery, University of Michigan

MOST of the infections of the lip and face do not give rise to serious symptoms, but heal spontaneously without treatment. Any infection of these parts is, however, potentially grave and may present a problem that taxes the skill of the surgeon to the utmost.

The face is so closely related to many important structures that a comprehensive presentation of the subject should include a discussion of infections of all of them. This is clearly beyond the scope of this paper and discussion will, therefore, be limited to infections of the lip and to some of the organs from which extension of infection may involve the face.

A facial infection may spread by one or more of 3 routes—*anatomical continuity*, the vascular system, and the lymphatic system. Since the proper diagnosis and treatment of facial infections requires an exact anatomical knowledge, the anatomical aspects of the subject will be emphasized in this article.

FASCIAE AND FASCIAL SPACES

Spread of infection by anatomical continuity is directed by 2 types of fascial planes, those associated with muscles and those associated with viscera and vessels. The fasciae that enclose the facial muscles though continuous with certain cervical fasciae form discrete potential spaces because these fasciae are attached to periosteum which creates a barrier between the facial and cervical spaces. Infection in these fascial spaces therefore tends to remain limited to them without spreading to the neck. The fasciae surrounding the viscera and vessels, however, form spaces that are continuous between the face and neck, with the result that infection may pass uninterrupted from the face to the neck or in the reverse direction.

In the face there are 3 muscular fascial spaces and 1 vascular visceral space. The superficial cervical muscular fascia, which encloses the sternocleidomastoid and trapezius

muscles, fuses above the hyoid bone with the middle muscular fascia, which splits to enclose the sternohyoid and omohyoid muscles. The fused fasciae ascend to the inferior border of the body of the mandible and there the tissue divides into a superficial and a deep layer. The superficial layer, shown in Figure 1, attaches to and reinforces the periosteum of the anterior aspect of the body of the mandible and also covers the masseter muscle and passes deep to the parotid gland, its ducts and the facial nerve and vessels. The deep division of the fused fasciae attaches to and reinforces the periosteum of the posterior aspect of the mandible (Fig. 2) and continues upward to surround the internal and external pterygoid muscles forming their fascial covering.

Space of the body of the mandible. On the free buccal portion of the mandible the periosteum is covered by the gingival mucous membrane while inferiorly the periosteum is reinforced by the above-mentioned fasciae and by muscle insertions. The fascial space between the superficial and deep divisions of the middle muscular fascia may be called the space of the body of the mandible (Fig. 4). It has an important relationship to infections of this bone. Because of fascial attachments osteomyelitis of the body of the mandible is barred from spreading either superficially or deeply. The infection may remain localized, may discharge into the mouth, or may spread to the masticator fascial space. The space of the body of the mandible may be drained through the mouth by means of an incision through the gingival mucous membrane of the vestibule or by an incision through the skin along the inferior border of the body of the mandible, which incision must be carried directly to the bone in order to open the space.

Masticator space. The second muscular fascial space is occupied by the ramus of the mandible and is bounded externally by the masseter muscle, internally by the pterygoid muscles, and superiorly by the temporal muscle. These structures, as already stated, are

duct, with irrigation of the duct system Desjardins has had good results from treatment by X ray but considers radium more convenient for the patient. Favorable results when they occur are noticed within 48 hours Blair (3) advises radical drainage of the lesion if it has progressed for 48 hours.

It would seem the part of wisdom to utilize the more conservative methods early and in the University Hospital we give treatment by radiotherapy either with radium or the X ray as soon as the swelling in the parotid is noticed. At the same time the duct is dilated so that drainage from that avenue may be possible. If however the lesion is not favorably affected by these methods, it is not wise to wait indefinitely for the appearance of fluctuation before instituting drainage of the gland. The parotid has a fibrous covering of such density that death from sepsis may occur before fluctuation is detectable. If the process is still active and progressive on the third to fourth day in spite of conservative treatment and if the patient's condition usually determined by the concomitant leucocytosis permits, the drainage already described should be carried out and the entire gland including the deep portion should be explored and drained.

VISCEROVASCULAR FASCIAL SPACES

The three muscular fascial spaces of the face have been briefly outlined in relation to their surgical importance. In Figure 9 is shown a surface projection of these spaces. The only viscerovascular space that need be considered in relation to the face is the lateral pharyngeal or pterygopharyngeal space which is shown in vertical and horizontal section in Figures 2 and 3. This space is of great importance to the otolaryngologist but is involved so frequently in cases of some of the more superficial infections that it must be briefly considered here. It is bounded anteriorly by the mesial wall of the masticator space, laterally by the parotid space, posteriorly by the carotid sheath and its contents and medially by the pharynx and its fascia. Above it is limited by the base of the skull and below by the submaxillary gland with its fascial sheath.

Infection of the pterygopharyngeal space as already indicated may result from such in-

fections in the lateral wall of the pharynx as tonsillitis or peritonsillar abscess. The space may become infected secondary to infections of the retropharyngeal or the parotid space, but not from the masticator space since the internal pterygoid muscle intervenes between these spaces.

Once infection has reached the lateral pharyngeal space the internal carotid artery is in danger of necrosis and the internal jugular vein is liable to septic thrombosis. It is apparent, therefore, that infections in the parotid gland may result in the grave complication of hemorrhage from the internal carotid artery or septic thrombosis of the internal jugular vein. Early drainage of parotid infections will often prevent infection of the pterygopharyngeal space. The space should be drained either internally through the lateral pharyngeal wall or externally as indicated in the description of the method of draining the deep portion of the parotid gland. If even a mild hemorrhage should occur the common carotid must be immediately ligated. Assisted at the outset infections in spaces formed by vascular fascial planes easily follow these planes in adjacent areas. Infection in the lateral pharyngeal space passes without hindrance into the carotid and jugular sheath and thence into the vascular fascial spaces of the neck and mediastinum.

Another small space of some surgical interest may be seen in Figure 3 between the jugular vein and the stylohyoid and digastric muscles. It contains lymph nodes of the deep cervical chain that drain the above mentioned regions and may be the site of severe lymphangitis and abscess formation which infection may extend along behind the carotid sheath to the supraclavicular fossa. Infection in the space between the jugular vein and the stylohyoid and digastric muscles gives rise to marked tenderness along anterior and posterior borders of the sternocleidomastoid muscle.

UPPER LIP AND NOSE

The last important region of the face to be considered is that bounded laterally by the masticator spaces, inferiorly by the lower border of the mandible and superiorly by the hair line. In this region lie the lips, nose, cheek,

palpebral regions, and forehead. The organs of the special senses present highly special problems that should not be considered here. This region is covered by loose skin and subcutaneous tissue. Underneath lie the muscles of expression that take origin from the bones of the face and that are inserted into the deep portion of the skin. These muscles do not have a fascial covering but are surrounded by subcutaneous tissue. Therefore in this region there are no fascial planes to limit infection, which spreads easily in the subcutaneous tissue.

A rich plexus of vessels lies deep to the muscles of expression, they, too, are surrounded by the subcutaneous tissue. The skin, being attached directly to the muscles of expression, is almost constantly in motion. In this respect it differs from the skin of the rest of the body. The relative immobility of the facial skin tends to prevent the localization of infection. The venous drainage of this portion of the face is collected by the facial vein and normally carried to the internal jugular vein. There are no valves in the veins of the face and their walls are less flaccid than those of other veins because of the firm support afforded by the sub-

Fig. 1. Dissection of the first muscular fascial plane of the face and neck, and its continuity. This plane can be seen deep to the parotid gland, its duct, and facial nerve and vessels. A. Skin B. conditions the venous blood from the face does not drain into the cavernous sinus. In Figure 10 is shown the course of the principal veins of the face and their communication with the superior ophthalmic vein and through

Fig. 5. Diagram of the face showing the deep and superficial temporal arteries and veins. (See text and Fig. 2.)

it with the cavernous sinus. When the facial vein or its tributaries are obstructed by thrombophlebitis or by pressure from oedema or exudate the current may be reversed and septic emboli may pass to the cavernous sinus, resulting in bacteremia, meningitis or sinus thrombosis. Progressive thrombosis of the facial angular, and superior ophthalmic veins may eventually reach the cavernous sinus. Infections of the upper lip, the external surface of the nose and the external nares are all ways in danger of developing these highly fatal complications.

Infections in the upper lip may be due to streptococci entering cracks and fissures at the junction of the nasal mucous membrane and the skin, in this case erysipelas of the face

results. A more serious type of infection arises from staphylococci with invasion of the skin and soft parts of the lip itself. Such an infection may range from tiny pustules to a carbuncle involving the entire face. Certainly the huge majority of pustules are self limited and cause no more than a slight annoyance. At any time injudicious treatment by patient or surgeon may change the clinical picture from a harmless lesion to one that may be rapidly fatal. It is well to emphasize the fact that bacteremia, meningitis and cavernous sinus thrombosis may develop from a traumatized pimple. Squeezing a pimple endeavoring to abort a pustule or furuncle by incision or by the introduction of an antiseptic may initiate the spread of infection by continuity

Fig. 7. Dissection showing the superficial portion of the parotid gland and its internal and external relations to the facial nerve. and by the blood stream. It is probable that the great majority of severe infections of the upper lip and nose were originally mild infections that were converted to severe infections by ill advised treatment.

TREATMENT OF INFECTIONS OF THE UPPER LIP

The treatment of these infections will vary in character with the location size and stage of the infection. First, no pimple or pustule no matter how small should be squeezed or traumatized. J. B. Brown's (4) suggestion of covering the pimple with adhesive plaster in order to splint and protect it seems a sound one. In from 1 to 2 days the lesion should have virtually disappeared.

Any infection larger than a pimple such as a furuncle or carbuncle in the lip and nose should be treated by bed rest in a hospital. The results obtained from radiotherapy, in the hands of many observers, is so favorable that some form of this therapy should be tried. It may abort the early lesions and break down the late ones. This treatment should be given at the earliest possible moment in order to produce the best results. When a carbuncle

exists every effort should be made to reduce the activity of the lip to a minimum. Talking should be prohibited and in extensive lesions feeding by a nasal tube should be used. A hot moist dressing gives comfort and perhaps aids in recovery.

When the process has extended more widely with the signs and symptoms of generalized infection present it is possible that septic thrombophlebitis is present and one is faced with deciding whether to ligate the angular vein. There is no unanimity of opinion on this question. Brown (4) writing from the service of Wilray Blair states that ligation of the angular vein is not practiced in that clinic. Schileau in 1910 and Bullock in 1912 reported a case of ligation of the facial vein for cellulitis of the lip with recovery. Roeder reports a favorable result from this procedure and Hamilton Bailey advocates the measure and reports 3 favorable cases. In the face of a lesion of such potential gravity it would seem advisable to carry out an operation of a minor nature such as this if there is a chance of preventing generalized infection or cavernous sinus thrombosis. If carefully performed with a small amount of local anesthesia, the procedure can hardly be said to increase the dangers of the disease. Bailey states that a sign which foretells impending danger is spreading edema from the lip to the inner canthus and this is usually found in the presence of suffusion of the eyelids. As far as my own observations have gone the premonition is invariably unilateral. If in addition to this sign there is considerable elevation of temperature the call for action is imperative.

Ligation of the angular vein can be easily carried out through a short incision carried down and slightly out from a point below the inner canthus along the junction of the nose and cheek. The angular vein is found lying in or under the fibers of the levator labii superioris alaeque nasi muscle. The operation is deserving of further trial in certain cases of infection that is progressing up the cheek and nose and whenever the presence of thrombophlebitis is suspected.

If frank pus is present in the upper lip drainage is usually advisable. Many pro-

Fig. 8 Schematic drawing of the face with projection of the bony landmarks, showing the incisions for infections of the parotid gland and temporal spaces

cedures have been suggested but the gentle and ample opening of the abscess with a cautery knife and the removal of free sloughs seems to be simple, rational, and adequate. A general anæsthesia should be used for any operation on the lip because local anæsthesia tends to spread the infection already present. The incision in the lip should be made nearest to the area of broken down tissue, sometimes it can be made on the inside of the mouth, thereby avoiding a visible scar. Carp reports excellent results following the circuminjection of the patient's blood; others substantiate his claims. Our experience with this method is too small to carry weight.

Should the infection become generalized or meningitis supervene the treatment is that of these complications. The occurrence of thrombosis of the cavernous sinus must be suspected if swelling of the eyelids and exophthalmos appear. Paralysis of the ocular muscles usually is present early in the process. Within a few days the second eye becomes involved. Operative attack on cavernous sinus thrombosis has been suggested and undertaken with rather unsatisfactory results. After the infection has passed beyond the face to

Fig. 9 Surface projection of the different anatomical spaces described.

the blood stream the prognosis is very grave and the result usually fatal. A comprehensive discussion of this is presented by Eagleton. It is possible that a satisfactory operative attack on the cavernous sinus may be devised but even this would not be applicable to many of the patients in whom meningitis and bacteraemia are also present.

INFECTIONS OF THE LOWER LIP

Infections in the lower lip arising either in its external or internal aspect, are less serious than those of the upper lip. Cavernous sinus thrombosis seldom occurs secondary to infection of the lower lip because the veins of the lower lip lie at a deeper level and are more efficiently splinted by bone and muscle, and the lower lip is much less mobile than the upper lip. Infections arising on the inner aspect of the lower lip from the lower gingival border along the lower incisor teeth and in the floor of the mouth may pass along the lymphatics from this area to well defined spaces lying above and below the geniohyoid muscles (Figs. 12 and 13). The superficial space lies between the geniohyoid and geniohyoid muscle. It is bounded laterally by the body of the mandible and is divided into 2 compartments by a median fascial septum. Another

FIG. 6. Dissection showing the course of the anterior facial vein and its anastomosis with the superior ophthalmic vein. (Adapted from Testut.)

FIG. 7. Dissection of the region where the angular vein may be ligated.

space lies deeper between the geniohyoid and the mylohyoid muscles. This is also bounded laterally by the body of the mandible and divided in the middle by the same fascial septum. Another potential space that may be involved lies between the mucous membrane and the genioglossus muscle in which lies the sublingual gland. Infection in the first mentioned areas gives rise to the clinical picture first described in 1836 by von Ludwig and still called Ludwig's angina.

Ludwig's angina. This infection gives rise to a clinical picture so constant and so severe that it has received much attention from surgeons. The diagnosis is made on the findings of an infectious process in the floor of the mouth in the spaces already described. There is an elevation of the tongue and redness and oedema of the mucous membrane over the

involved area. The infection may be unilateral when the tongue is pushed to the opposite side, or it may be bilateral when it is pushed toward the roof of the mouth. The redness and edema of the mucous membrane of the floor of the mouth are marked, pressure of the swollen mucous membrane against the teeth often leaves an imprint. Discomfort is marked, swallowing is difficult, and speech becomes guttural. There is dribbling of saliva and the respirations become embarrassed. Dysphagia is not uncommon. There is a board like swelling externally in the anterior aspect of the neck. There is no point of fluctuation and although the infection may be limited at first soon it envelops the neck from side to side. The systemic reaction is often severe. Complications may arise from local or general extension of the infection.

Many papers have been written on the differential diagnosis of deep cellulitis of the neck and Ludwig's angina. It is highly probable that such a differential diagnosis is impossible since it is more than likely that there is no such original clinical entity as deep cellulitis of the neck. Infection always has a

definite origin and always spreads along certain planes. If neglected, infection may of course break through the anatomical barriers but originally it had definite boundaries and was a definite clinical entity.

The treatment of Ludwig's angina consists in early surgical drainage of the infected area. The technique of operation varies according

Fig. 13. Frontal section through mouth showing floor of mouth divided by median fascial septum indicated by crosses. (Courtesy Dr A. C. Furstenberg)

to the location of the infection which is not always easily determined. If the abscess is below the geniohyoid muscles the region under the chin is prominent and occasionally gives rise to fluctuation. An incision should be made through the skin subcutaneous tissue and mylohyoid muscle into the abscess cavity as shown in Figure 14 and drainage tube introduced. When the swelling is uniform the incision should follow the lower border of the mandible so as to give access to both sides of the median fascial septum inasmuch as one cannot always tell accurately from examination which side is involved.

If the abscess is located above the geniohyoid muscle it may point under the tongue and can be drained easily through the floor of the mouth, the incision passing through the mucous membrane and the genioglossus muscle as shown in Figure 15. The spaces on both sides must be explored. Blind exploration with a blunt instrument may fail to open a small abscess, but accurate dissection of the involved spaces usually will. When a neglected Ludwig's angina breaks through the walls of these spaces, it usually breaks into the lateral pharyngeal fossa with the signs, symptoms, and complications already discussed in connection with that space.

The anatomical studies of the fascial spaces that have been made by M. Paul Truffert of Paris and by Prof. E. Stincer of the University of Havana have been of exceptional value to us.

SUMMARY

1. Facial infections may spread by direct continuity or by the hematopoietic or lymphatic systems, or by a combination of these routes.

2. When the spread occurs by continuity its direction is determined by 3 fascial planes that enclose spaces which are anatomically described.

3. Infections in the mandible are usually limited by the so called mandibular space though extension may occur to the masticator space.

4. The masticator space may also become involved by infection of the zygoma and temporal bone. Methods of drainage of this space are considered.

5. Routes of spread of infection from supuration of the parotid gland and appropriate methods of drainage are discussed.

6. Infection of the upper lip and nose may cause thrombosis of the adjacent veins with resulting reversal of the venous flow. Infection or even thrombosis may then travel to the cavernous sinus. Infection of the lower lip may involve the spaces in the floor of the mouth and result in Ludwig's angina. This condition should first be treated conservatively but wide surgical drainage may become necessary.

Discussion

DR. ELLIOTT C. CUTLER, Boston Dr. Collier has covered his topic in an admirable fashion and clearly indicated an important lesson for the surgeon. He has pointed out that in this field, as elsewhere the chief lesson tells us when not to indulge in surgery and points out that simple infections often need the greatest care and wisdom. This emphasizes the importance of so called minor surgery and the fact that such conditions need the advice and care of the senior members of hospital staffs and should not be delegated to junior assistants. Too often we see septic hands and infections of the face cared for as ambulatory dispensary cases until it is too late. Our distinguished past President Dr. Allen Kanavel and his pupils have pointed to a great lesson in emphasizing the dangers of infections of the hand and how to care for them. Dr. Collier makes a beginning for infections of the face the seriousness of which is often recognized too late.

In an attempt to further Dr. Collier's lesson I shall consume my brief time in discussing *cavernous sinus thrombosis* a none too rare and usually fatal complication of infections about the lip and nose. The infrequency of reports concerning this condition indicates not so much the infrequency of the condition as its hopelessness. The very triviality of the original lesion often lulls both the physician and the surgeon into a false sense of security. Thus one of the patients in our Peter Bent Brigham Hospital series was a nurse. A small furuncle appeared at

the corner of her lip the patient opened this with a needle in 6 days she was dead with classical signs of cavernous sinus thrombosis. Another case in this series began as a simple pimple just below the eye. This rapidly became a carbuncle. After 4 days observation in the hospital and 13 days after the first pimple appeared excision with endothermy was carried out. The patient succumbed 6 days later with signs of disseminated sepsis including cavernous sinus thrombosis. A third case in the Brigham Hospital series was a member of the resident staff of a neighboring hospital, who acquired a small furuncle at the base of one hair in his mustache only 4 days before this lesion had spread to the whole lip and into the sinus and caused death. The fourth and fifth cases in my private series resulted from simple trauma. The first was a young boy struck by a baseball who suffered a small contusion of his malar prominence and the second was a little girl whose sister had slammed the door on her face giving her a similar tiny laceration over the malar prominence. Streptococci entered these small abrasions. Within a few days swollen eyelids, fixed eyeballs, choked disc, and stiffness of the neck ushered in the fatal result.

The danger of such a complication is visualized by a study of the anatomy of the parts and it is perhaps fitting that Dr. Collier having emphasized fascial planes, I should emphasize the danger of blood vessel extension. The accompanying figures em-

FIGS. 1 AND 2. Note anastomosis at upper inner angle of eye between superficial vessels and the superior ophthalmic vein, and the connection between the deep pterygoid vessels and inferior ophthalmic vein. None of these veins has valves.

Fig. 3. Transverse view cavernous sinus. Note break up of sinus into innumerable contiguous compartments which greatly impede the flow of blood. Also note position of third, fourth, and sixth nerves and how easily disease of the sinus may affect them.

phasize the anatomical extension of the infection by way of blood vessels. The major peripheral orbital tributary of the cavernous sinus is the superior ophthalmic vein. This unites at the inner upper angle of the eye with the angular vein, the supra-orbital vessels, and the nasal vessels and other tributaries from the face and lip. But also there are fine anastomoses between facial vein branches and the inferior orbital vein, and deeper in communications exist between the pterygomaxillary veins and the cavernous sinus. Moreover none of these vessels carries valves and the flow of blood is slow and often reversed. Phlebitis of any of these superficial vessels may lead to extension into the cavernous sinus. We all recognize that trauma with injury of the intima, infection, and stasis play the major rôles when thrombosis results. For some good reason perhaps not well understood but possibly to prevent respiration from exerting too sudden an effect upon intracranial pressure, the cavernous sinus has a peculiar construction. It is cut up into many contiguous compartments which must greatly impede the flow of blood. This may be excellent for the purpose of buffering the intracranial tension against sudden shifts due to respiratory changes, but it also creates a most admirable condition for the extension of thrombophlebitis. When an infection is in the extremity we are not brought face to face with the great extension of thrombosis unless there be a resultant edema of the extremity or a

subsequent pulmonary embolus. But when the extension occurs into such an important anatomical part as the cavernous sinus, where the mechanical arrangement of the sinuses and the important structures lying near it call forth immediate clinical signs, then it early assumes an alarming picture. The danger of such an extending phlebitis in relation to the face has long been recognized and surgeons have learned to withhold mechanical intervention whenever possible. Surgery, by opening into vessels beyond the natural "walling-off" process, may permit bacteria to enter tributaries draining into the sinus. As cavernous sinus thrombosis progresses, the extra-ocular muscles become paralyzed by involvement of the nerves lying in the sheath of the sinus, vision is lost from thrombosis of the ophthalmic vein, and this is preceded by an ominous choked disc.

There is no suitable therapy for cavernous sinus thrombosis, though one finds occasional reports of cases where almost superhuman surgery has seemed to save a life. Thus there is a report by Browder of Brooklyn¹ telling how, in the face of seemingly definite thrombosis of the cavernous sinus on one side, he opened the cranium and completely obliterated the cavernous sinus on the affected side by the use of electrocoagulation. This apparently stopped the progress of the infection and, though his patient lost the eye, life was saved. A similar extensive procedure has been proposed by Eagleston² recently, the approach to the sinus being through the eye. This author also reports successful cases. Less radical surgery has on the whole proved meddlesome and costly. In a series of 23 cases treated in the wards of the Peter Bent Brigham Hospital for serious infections of the lip, nose or cheek—either carbuncle or cellulitis—there was a mortality of 30.4 per cent. In 10 of these cases some simple surgical procedure was carried out. In this group the mortality was 50 per cent against 21.7 per cent in the untreated group. And a study of the records showed no great difference in the cases.

Prevention of such a complication is what we most desire and in view of the anatomical considerations it seems wisest to urge conservatism for the moment in the treatment of spreading infections, arising in the lip, nose or close to the eye, particularly if the streptococcus is the etiological agent. Such conservative treatment will consist of heat to the local part and general care to the patient.

EXPERIENCES WITH TUBED PEDICLE FLAPS¹

DR HAROLD GILLIES C.B.E. F.R.C.S., F.A.C.S. (HON.) LONDON ENGLAND

Plastic Surgeon to St. Bartholomew's Hospital, London; the London County Council, the Royal Air Force; St. Andrew's Hospital, Dublin Hill and the North Staffordshire Royal Infirmary Newcastle-under-Lyme

A TUBED pedicle flap is a type of delayed flap in the form of a tube in which the long edges are sewed together. It is thus completely separated from its bed except at the two attached ends and is not replaced, as is a delayed flap. As for all types of delayed flap the object of the procedure is to induce a blood supply parallel to the long axis of the flap. The tubed flap is different from the other forms of delayed flap in that it prevents any form of granulation or scar tissue formation on its deep surface.

It was first described by Filatoff in 1917 (1), but the idea occurred to me quite independently in the same year (3). Its immense usefulness was immediately recognized by my colleagues in the War at Sidcup. It has since undergone many modifications and its field of usefulness has been extended. In the process its limitations have also been more accurately defined (4).

GENERAL CONSIDERATIONS

The rationale of the flap is to increase its longitudinal blood supply at the expense of the transverse so that it can survive on the blood supply of one end only. The idea is by no means new and the original Taghiocotian (6) operation was a simple delayed flap. Other forms of delayed flap tend to produce considerable contraction from granulation tissue on the deep surface. The time factor is also different from that of the usual delayed flap as in my own experience I seldom if ever, trust the blood supply at one end of the flap until a minimum interval of 3 weeks. Lymph stasis in the flap is also one to which consideration should be paid some of the "tubes" undoubtedly show this condition and if so they can be left a further interval of time until the lymphatic circulation is established, their subsequent success as regards viability, adaptability and cosmetic effect is considerably enhanced. In a long established tubed

pedicle, which has had many removes great liberties can be taken with its blood supply

ADVANTAGES

Its chief advantage lies in the readiness and safety with which large quantities of skin may be transported from a distance. The tubed pedicle having been successfully made its size can be increased either laterally or longitudinally so that huge quantities of skin can safely be transplanted. It is of particular use where no massive direct flap is available such as is usually used when body skin is transferred directly to the arm or forearm. Another of the characteristics of a tubed pedicle is that when once established its flexibility allows it to be twisted and turned in the most liberal manner without causing anxiety as to its viability. It lends itself to temporary attachment through an intermediate host.

When the wrist is used as a means of conveying a large abdominal tubed pedicle flap one has given it an additional mobile pedicle whose base may now be considered to be at the shoulder. The flap can therefore be carried to any position of the body from the sole of the foot to the crown of the head or to any intermediate portion. The use of the wrist as an intermediate host is a great step in advance over the caterpillar method. Its viability has already been stressed. As a cosmetic flap it is at least up to the standard of any other type of flap except in one or two specific restorations.

DISADVANTAGES

The chief disadvantage is the time factor which includes the financial aspect. For example, the shortest time that an abdominal flap can be transported to the neck works out in practice as shown in Table I.

Factors increasing the time. When flaps larger than say 8 by 3 inches are required or when there are branch extensions of the flap some provision must be made for safeguarding the blood supply of these elongated masses such

the end of the pedicle that is about to be
moved. Further the wrist is frequently in-
serted into the middle of the flap rather than
to one of its extremities, in order that the blood
supply can flow equally to either end. All
these minor variations require extra time and
extra operation stages. The financial outlook
therefore both for patient and surgeon is not a
rosy one. The time factor required from the

the whole of the left cheek. Separate nasal reconstruction

surgeon is also serious as experience shows that to hustle any of the stages leads inevitably to an eventual delay or disappointment. Many stages, however, can quite adequately be performed by a well trained junior.

The other disadvantages of the flap are connected in my opinion with failure of the operator to observe the principles of technique, thus he may shorten the interval he may misjudge the viability of the flap, he may sew it up too tightly or in some other way interfere with its blood supply. If he fails to remove the

fibrous tissue in the unrolling process, full functional cosmetic success will not be obtained. Disappointments may also occur owing to a faulty plan in the first place.

If, however the technique has been carefully observed, both patient and surgeon will have a pleasant surprise in finding that the flap fits and looks well in its new bed.

TECHNICAL DETAILS

The plan As I have stressed many times an accurate diagnosis of the loss of skin should

Fig. 4. Excision of jaw and soft tissues of chin and lip by Mr. Gordon Taylor (London). Plastic repair by double

crossed tubed pedicles. Bone graft and trimming. Unflamed

first be made. Due allowance should be included in this estimate for the retraction or replacement of normal tissues into their normal position when the scar has been excised. Many experienced operators frequently fail to realize the full extent of the loss. A great help can be obtained in this diagnosis, as in any other, by comparing the sound with the unsound side of the body or comparing the damaged part with a normal one. A model is now made of the exact loss in sterilizable material. I have published recently a technique for design of direct flaps which will be found eminently suitable for the tubed pedicle variety (5).

It is as well to cut the flap very slightly on the liberal side so as to allow for a final excision of its margins, also for the ease of adaptation in certain situations an extra length of pedicle should be added to the flap proper.

Some rules as to judgment of the proportion of these flaps must be given. Thus a flap that was 8 inches long and only 2 inches broad would in my opinion, be dangerous to make at one sitting. Any flap of longer than 8 inches of any width should not be made at a single venture. There enters the problem of the actual vitality of the skin of the patient under consideration. This is a factor in which only experience can assist in the decision.

Incisions. Parallel incisions to the extent designed are made through the skin and subcutaneous tissues. Again judgment must come into play as to the amount of fat to be included both as regards the restoration required and the presence or absence of a large quantity of subcutaneous fat. In spare

subjects, for instance, the incision can be carried down to the subcutaneous fascia with advantage to the viability of the flap and to the rapidity and ease of its manipulation. In a fat subject however the inclusion of such a quantity would be deleterious to the final result and would make the future of the flap a matter of some difficulty and be of considerable immediate peril to its blood supply. A thought occurs to me in regard to blood supply in fat patients that there is only a limited quantity of blood supply to an individual area, which in the presence of the fat is dissipated before it enters the skin. Consequently in obese subjects I would issue this note of warning to be more patiently conservative than in the thin. The length of the primary tubing can also be varied according to the actual site from which the flap has been taken. Thus a flap in the oblique inguinal region or one more vertically parallel to the main vessels of the abdominal wall can be cut with a greater margin of safety than one which crosses the middle line either above or below the umbilicus, or traverses the middle line of the chest. Flaps whose base lies in the region of a natural anastomosis such as the axillary can, therefore be cut with confidence.

Sites. The common donor sites are the oblique inguinal single or double the vertical abdominal the acromiopectoral single or double the less common sites are the neck, the back of the shoulder the outer aspect of the arm and the outer and anterior aspects of the thigh.

Suture. As the skin edges are rolled together there is a tendency for fat to protrude. It

Fig. 5 Example of branched pedicle. The branch is for the upper lip, the extremity for the nose, and the neck portion for the cheek

Fig 6 Example of one pedicle flap (temporal artery) conveying another tubed pedicle (acromial) to the nose

should be trimmed with scissors and as the suture progresses the action of the thumb in advance of the suture will effectually prevent the interpolation of fat between the skin edges. After the flap has been cut and its undersurface carefully examined for bleeding points, a decision is made as to how much of the flap can be tubed without undue tension at either end. A fine hook is passed through the skin at the commencing point and the skin of that side dragged through into juxtaposition with the corresponding point on the near side. A first interrupted suture is placed

and held as a stay. A similar procedure is adopted at the other end. The two edges of skin are now presented to the operator and may be sutured with ease. If the flap is to be used in an exposed position it is well to make this suture with a subcuticular stitch, using an eyeless needle. At all times avoid damag- ing the skin with dissecting forceps

Closure of the secondary wound. A decision now has to be made as to whether the wound can be closed by direct approximation beneath the pedicle or not, such a closure is usually available in the abdominal wounds as well as in the acromiopectoral. Free undermining of the surrounding skin and positioning of the thigh or the arm will materially aid this clo-

Fig. 14. A huge tubed pedicle flap from outer aspect of buttock and thigh to make skin clothing for damaged leg.

sure. Deep catgut sutures relieve the tension and interrupted silkworm sutures are placed through the skin.

At the place where the tubed pedicle leaves the abdomen at either end will now be found a triangular raw area. There will likewise be found a similar raw area in the abdominal wound. The apices of the two triangles are approximated by a special suture. The needle is passed through the skin of one side of the abdominal edge, emerging in the subcuticular area. It is continued as a subcuticular stitch first down one side and then up the other of the apex of the tubed pedicle triangle, finally it emerges opposite its entrance at the apex of the abdominal triangle. When tied, the two triangles are accurately approximated. When there is no possibility of a satisfactory secondary closure the raw area may be left

Fig. 15. a, Right inguinal tubed pedicle flap applied direct to inner aspect of thigh for severe traumatic loss. b, Pedicle lengthened across the abdomen to left iliac crest, note the umbilicus in flap. c, After 3 months interval this very long pedicle divided and spread over remaining raw area. d, Note final position of umbilicus. e, The secondary repair.

to granulate or be grafted with a free razor graft.

There are certain modifications of technique for *very large* or *very broad* flaps. The size of the amount that may be tubed at the first intervention has already been indicated. If further skin is required the tubing process may be continued at the end of 10 days to a fortnight. The same remarks apply on the occasions when a branch tube is run sideways from the main tube. When the flap is very broad it may frequently be found advisable to make a square-ended implantation into the forearm as the first stage and to follow this up by tubing the broad flap 14 days later.

Dressing. Further to safeguard the secondary closure the skin is treated with mastisol and gauze applied from side to side beneath the pedicle. Two gauze rolls are now placed parallel to the tubed pedicle to safeguard it from any undue pressure and yet to allow of inspection for the presence of hæmatoma or the progress of the circulation.

A pedicle should be examined the same evening and at frequent stages. Any hæmatoma should be freely expressed and if the vitality of the flap be endangered for any reason warm saline dressings should be applied at very frequent intervals. At all stages massage of the flap is of considerable value.

THE FIRST REMOVE

For a simple pedicle of not more than 8 inches it should be possible to detach one end after an interval of 3 weeks. This time will have to be increased if there has been any hitch or if the pedicle is of greater dimension. In severing the end designed to be moved first, care must be taken not to include any considerable portion of skin which was not tubed in the first instance and is therefore devoid of an already established longitudinal blood supply. If insufficient of the flap has been "tubed" at the first occasion the extra bit must either be "delayed" or further "tubed" prior to its being cut off. The raw

Fig. 6 Use of thigh as intermediate host for transference of abdominal pedicle to opposite leg

end of the pedicle is now free in the air and is approximated to its next home. When the process is direct such as in an acromipectoral flap to the cheek or nose just so much of the pedicle is opened out as is convenient for the restoration or safe from a blood supply point of view. For instance, it is not usually safe to open a pedicle more than half its length. When the free end of the pedicle is to be grafted into an intermediate host as the wrist, very little of the pedicle need be opened out say 1 inch.

The opening out process. The pedicle flap is held in the hand with the seam uppermost and the extremity of the raw area retracted with fine hooks by an assistant. The seam being kept central a fine knife is used to excise or incise this seam until the pedicle opens out. It is essential that the opening out of the pedicle should be done on the same line as that in which it was closed.

The blood mark. A convenient method of design for implanting the open end of the

pedicle is by squeezing it, say on the back of the wrist to which it is to be attached. This makes a blood mark of the exact size of the raw area of the pedicle. If now half of this blood mark be turned backward toward the pedicle the two areas when sutured together should be approximately equal. Again care must be taken to prevent hematoma formation. In addition to tying the vessels, it is as well to put in two deep catgut sutures to approximate the fat of the two areas. Care, even in this maneuver must be taken also for I have known quite a number of cases in which their presence has constricted the blood supply to part of the flap. Suture of the skin edges of this stage is usually by interrupted, occasionally by blanket method.

SECOND REMOVE

The second of the two original attachments of the flap is now divided. If the pedicle be of reasonable proportion that end of the flap

Fig. 17 Neck pedicle including active platysma lifting a weight by voluntary contraction.

may be divided in a similar manner to the first, but if unduly large or not fully 'tubed' the extra precautions noted before must be taken. The interval of time between the first and second remove must not be less than 3 weeks before final division. In a simple case by the direct method from the acromial region, a pedicle can be carefully opened by excising its little joining scar, and the whole flap embedded into its final position. More commonly it is wise not to open the whole of the pedicle at this stage but to leave some minor adjustments for a future occasion. When an intermediate host has been used the second remove corresponds in all particulars to the first by the direct method while the third after an interval of 2 to 3 weeks is carried out similarly to the final stage of the direct. Should there be for any reason any long delay say 2 or 3 months in between any of the stages the subsequent maneuvers will be all the easier.

Variations When the patient is in no hurry and finds the fixation of his arm to the abdomen irksome at the end of the second stage instead of bringing the free end of the pedicle up to the neck or face it may be implanted into the forearm alongside its fellow, where it can rest happily to await the return of the patient or perhaps the surgeon from a holiday. When the pedicle is very large bilateral, or has a branch pedicle attached, it will be found convenient to attach the wrist to the opened out middle portion of the pedicle. This

Fig. 18 Example of central necrosis due partly to crossing mid abdominal line

enables the blood supply from the wrist to wander evenly through to the extremities of the pedicle, and when such a pedicle is taken say to the neck two free ends are available attached by their middle to the wrist. The free ends are therefore sewed to the back of the neck and the final stage made when the wrist is detached from the middle of the pedicle. Warning must here be given that in such a central attachment of the pedicle to the wrist, the implantation must be very near the wrist joint or back of hand if that pedicle is going to be used for the neck (see Fig. 10). If the center of the pedicle is allowed to be attached further up the forearm a number of troublesome complications are likely to occur.

A broad attachment of the pedicle to the radial border of the forearm is indicated only in cases of repair of one side of the face above the mandible.

EXPERIENCES COMMON AND UNCOMMON

Tubed pedicle flaps have been used by me for the successful closure of a pharyngeal fistula to form the outer covering for hypospadias repair for the repair of the penis after phagedenic ulceration and after accidental avulsion of its skin, for vesicovaginal fistule, and by other surgeons for other unusual conditions. I have designed a tubed pedicle for remaking of a breast after amputation. In one tubed pedicle of the neck I included the platysma muscle with its nerve supply intact. The curious phenomenon of this patient being able to raise a weight by voluntary contraction of the pedicle is an interesting study. Branch pedicles have been used either direct

acromiopectoral or abdominal via the wrist for such conditions as both sides of the scalp and forehead the forehead and nose the cheek and chin or the cheek and upper lip and for a complete neck. On three occasions pedicles have been implanted into another pedicle as its intermediate host a particularly good one being the turned down temporal artery flap attached to an acromial. A most remarkable study in viability of these flaps occurred in a case in which two long pedicles were joined end to end. When one end was finally detached the circulation from the upper end of the first pedicle was entirely adequate to penetrate through a very poor joining scar right to the extremity of the second pedicle. It is found convenient occasionally to cross-cross two pedicles or to cross over the free ends of a long pedicle. These maneuvers are dictated by expediency and opportunism. A special method of making the nose from an acromiopectoral flap is to detach the acromial end and to suture it to the palmar aspect of the opposite wrist in such a way that when the back of the hand is placed on the forehead the pedicle will be hanging straight down the nose with its

joining seam facing backward. Examples could also be enumerated of transferring the pedicle via the wrist to the knee or lower and of using the opposite thigh as an intermediate host for areas below the knee. One of the longest pedicles I have ever made went from side to side of the abdomen including the umbilicus. It was tubed in two stages, the second stage after the first implantation had been successfully grafted into the thigh. After the second half had been tubed the flap extended from the region of the inner condyle of the right femur to the left iliac crest about two-thirds of it being in the air. The umbilicus was seen to adorn its middle and eventually to end up somewhere above the knee, an unusual place in which to carry the navel.

Discussion

Dr. CHARLES G. MINTER, Boston. We are all doubtless familiar with Sir Harold Gillies' work in plastic surgery. His accomplishments in reconstruction of severe facial injuries was one of the outstanding contributions of the War. It was he who popularized the transference of large areas of skin obtained from distant locations by the tube graft method and placed it in the hands of the profession as a most useful procedure. Formerly in my service at the Children's Hospital I had an opportunity of using this method freely and with satisfaction, chiefly in the correction of deformities following burns. In large part these deformities occurred in girls due to the inflammable nature of their dresses. Contractures of the extremities, aniles and in particular the neck, have yielded eminently satisfactory results under this method. In late years, the better understanding of the Z method of utilizing the scar tissue web has, to an extent, supplanted the tube graft but in broad contracted contractures the latter is the method of choice in my opinion.

The use of the tube graft has not been invariably successful in my hands. Ischemia is the most potent cause of failure. Too great length in comparison to the width of the rectangular flap raised for construction of the tube, too tight suture about the enfolded

subcutaneous tissue and too early transference of one end to its new location are among the causes of diminished blood supply.

In my experience, relief of the broad contracting scars of the neck following burns is most satisfactorily obtained by the tube graft method. The lesson usually occurs in girls and the choice of site from which to make the transfer with a minimum of visible scarring is difficult, as no one can forget how far the present trend in feminine fashions may ultimately lead its votaries. The lower lateral aspect of the chest wall seems the most suitable situation.

In conclusion I should like to express to Sir Harold our sincere appreciation of his brilliant work in this field and thank him for his kindness in presenting his views on the subject tonight.

ERNEST M. DALAND, M.D., Boston. The development of the tube pedicle graft has solved many plastic problems. The speaker has been too modest in regard to his part in the origin and development of this method. It is he who has put it into practice and he who has had the courage to try out new applications for its use.

In selecting a site for the graft it is essential to remember whether the skin used is going to grow hair

or not. If the graft is going to become a lining for a cheek, it is essential that there be no hair on it. If the graft is to form a covering for a man's cheek it is desirable that there should be hair on it.

Most of us have had cases in which we have used the tube pedicle graft successfully. Some of us have had failures. I wish to point out some of the reasons for these failures.

1 The tube has been made too long in proportion to its width. Sir Harold sets 8 inches for the maximum length but then only if conditions are ideal. If not a full 3 inches of width is available, the length must be less than 8 inches.

2 The tube graft has been too narrow.

3 Too much fat has been used in the flap. The tube edges should come together without tension. Too much fat will cause eversion of the skin edges. The secondary swelling and lymph stasis will shut off the circulation and the flap will die.

4. Too little fat in the flap will likewise cause trouble. In a patient with no subcutaneous fat, the pedicle method is probably not the best.

5 The flap has been cut too close to the midline or has crossed over the midline. Occasionally a flap may be constructed that crosses the midline but it should be made slowly and not made too long at the first stage.

6 Infection will produce necrosis and scarring and interfere with the circulation.

7 The dressing may be applied too tight over the tube pedicle flap. This may cause thrombosis and necrosis.

8 The transfer of the flap may be made too early. Three weeks is usually early enough, unless the flap is very short.

9 Finally in moving the graft to its new position I find that tissue that has been heavily irradiated makes a very poor host. In fighting the irradiation reaction, all the collateral circulation has been called on. As a result, little circulation goes into the graft and healing if it occurs at all, is delayed.

If a few of these precautions are followed I am sure that we shall all be satisfied with the results which we obtain.

PHAGEDENIC ULCERATION—ITS RECOGNITION AND TREATMENT¹

EMILE HOLMIAN M.D. F.A.C.S. SAN FRANCISCO CALIFORNIA

From the Department of Surgery, Stanford University Medical School

Phage devour, cancer Phageo to eat

SINCE Cullen's arresting description of his experience with a particularly stubborn infection following incision of an abdominal wall abscess, presumably appendiceal in origin, numerous similar experiences have been frankly and courageously recounted by perhaps somewhat chastened surgeons. The picture is much the same in each instance following drainage of an abscess, whether of the abdomen or chest (Fig. 1) there has occurred a slowly but insidiously progressive destruction of the skin before which the surgeon has for a time stood completely helpless, baffled because none of the usual and known bactericidal agents—chemical or physical—seemed to have the slightest influence in controlling the infection and served only to strike terror to the patient through their extreme painfulness. No other experience is calculated to be so effectively humiliating nor likely to fill one with a greater sense of futility as to see the precious covering of the body in spite of anything one may do slowly but surely recede before the relentless advance of invading organisms. They seem literally to eat away the skin. The disease is characterized by a remarkable chronicity. Until its final stages it is not fulminating nor unusually prostrating following the development and drainage of the initial infection; it is usually not attended by severe constitutional symptoms. But inexorable in its advance and apparently inevitably progressive it is completely demoralizing to a patient who in full possession of all his faculties, is subconsciously aware of the helplessness that weighs heavily upon his attending physician. Ordinarily nature is very kind in dulling the sensorium of the acutely and gravely ill patient so that little remembrance remains of a particularly trying period. In this disease the patient shares the apprehension of the doctor and too often his morale is completely broken. He awaits the dressing with terror and begs to be let alone.

He prefers death to the harrowing experience of the daily dressings. Fortunately Cullen's opportune rediscovery of the cautery and Baer's courageous application of maggots in combating stubborn infections have provided a very satisfactory way out. The problem is to recognize the lesion and to apply the proper therapy at the right time.

An analysis of the recorded cases reveals some instructive facts. By far the greater number have followed the drainage of intra-abdominal abscesses usually appendiceal in origin. The accompanying table (Table I) presents a brief résumé of the recorded experiences. Sixteen cases followed the draining of a ruptured appendix, one case followed a caecostomy for carcinoma of the sigmoid, another followed drainage of a subphrenic abscess complicating a perforated duodenal ulcer, another followed drainage of an encapsulated empyema complicating appendectomy with drainage, another followed drainage of an empyema complicating a pulmonary abscess, one case followed drainage of an empyema complicating pneumonia, one case followed the draining of an abscess of the breast, and one case followed an infection of the abdominal wall in a gardener subject to contact with organisms found in the soil and in fertilizers.

The last named case deserves more comprehensive comment. Luckett in 1909 advocated and performed canterly excision for a spreading phagedenic ulceration of the abdominal wall. The patient was a gardener who had picked a small pustule with his fingernail within 10 days an ulcer $5\frac{1}{4}$ by $10\frac{3}{4}$ inches had developed over the abdomen with astonishing rapidity and much pain. Excision of the edges by the Paquelin cautery was followed by prompt healing. The cultures yielded only a *Staphylococcus aureus* both in the aerobic and anaerobic cultures. The hospital pathologist Dr. Humphreys made the fol-

Fig. 1. Remarkable progressive ulceration of thoracic wall following drainage of empyema complicating a pulmonary abscess (Christopher)

lowing arresting suggestions "In my opinion the infection probably belongs to the heterogeneous class known as soil or dirt infection to which belongs chancroid phagedena malignant oedema etc. The organisms of this class in general are anaerobic spore bearers inhabiting rich soil etc. Owing to the difficulties of artificial cultivation their specific characters are but little known. The staphylococci are probably of only secondary significance."

The following 4 cases are added to this growing list of experiences with a slowly but irresistibly advancing infection which as yet remains somewhat obscure in its origin which is peculiarly resistant to all forms of therapy but which yields to cauterization, débridement, when applicable and to maggot therapy.

CASE I. M. S. aged 25 a single female while working in a garden in December 1930, developed a blood blister on the palm of the left hand. The

blister was opened but was not dressed, and she continued her work with fertilizers and soil without protection of the wound. This healed after temporary soreness but 2 months later a tender mass appeared in the left axilla which was incised and drained on February 6 1931. The culture is said to have yielded a streptococcus. Due to non healing a second incision was made in April for the evacuation of pus and the removal of necrotic gland tissue.

The discharge of pus continued however and the wound instead of improving grew larger. When first seen on July 21 1931 8 months after the beginning of trouble there was a dirty looking wound about 6 by 4 centimeters with an abscess cavity leading up underneath the pectoral muscle toward the apex of the axilla. The 2 incisions made 3 and 5 months previously were unhealed and discharging pus. The edges of the wound were distressingly painful to all the known antiseptics most of which had been given a trial and found ineffectual.

Direct sunlight irrigation with 5 per cent salt solution, and the occasional application of Berwick's dye during the next 2 months caused slight but definite improvement. Slow progress prompted admission to the hospital on September 15 1931. At this time the red cells numbered 4 180 000.

Fig. 2. December 9, 1931. Appearance of an axillary wound 1 month after incision of abscess. Note the progressive ulceration below the incision and the secondary ulceration posteriorly. b. October 4, 1932. Complete healing without fibrous contraction.

hemoglobin, 95 per cent and the white cells 13,600 of which 79 per cent were polynuclears, 12 per cent lymphocytes and 8 per cent large mononuclears.

Cultures on October 12 from the original wound disclosed a pure growth of hemolytic streptococci.

Under observation an instructive development occurred. Below and posterior to the original wound, in an area bathed by pus, there appeared a small pustule which looked like an ordinary hair follicle infection. After discharging a central slough or core, the resulting wound spread slowly but insidiously through a gradual necrosis of the wound edge until it was 3 centimeters in diameter. Subsequent cultures showed in addition to the hemolytic streptococci, the presence of the *Staphylococcus aureus* and a non-virulent diphtheroid bacillus. Special cultures from beneath the undermined skin established the absence of anaerobes.

During a 6 weeks' stay in the hospital, the treatment consisted of forced nourishment, rich in vitamins; irrigation with hypertonic salt solution and the daily exposure to the quartz lamp. For a few days on one occasion, an erysipeloid bluish spread forward from the wound over the left breast but subsided rather promptly. The administration of 50 cubic centimeters of anti streptococcus serum produced a violent reaction at site of injection in the left thigh but no sloughing occurred as in the Arthus phenomenon. Following her discharge from the hospital on October 26, 1931, the patient underwent treatment of the wound with a bacteriophage for 8 weeks without improvement.

The patient was readmitted on December 18, 1931, for the purpose of undergoing treatment with maggots. In the meantime the 2 wounds had spread slowly but gradually through an advancing necrosis of the skin edge (Fig. 2). The denuded surface was covered with a dirty looking pus, the edges were slightly raised, infiltrated and firm, undermined for about 4 millimeters and of a dusky bluish discoloration fading through red into the normal color about 1 centimeter from the edge. There was no macroscopical gangrene or necrosis.

One thousand maggots were introduced into the wounds on December 19, 1931, and a second lot of 1,000 on December 24. These caused a violent reaction in the tissues, as shown by marked edema and considerable purulent discharge. The temperature rose to 40 degrees C and liberal doses of pantopon, alternating with sodium amylal, were necessary to keep the patient comfortable. The violent reaction in the wounds, the high fever and the great discomfort prompted removal of maggots on December 26. The edema and fever promptly subsided and the wounds showed marked improvement.

On December 31, 1,000 maggots were again introduced into the wounds, but removed on January 3. The patient was dismissed on January 6, the wounds looking very much improved.

On March 7 the patient was re-admitted because of the persistence of a deep axillary wound. The superficial ulceration posterior to the axillary wound was healed. One thousand maggots were introduced into the axillary wound on March 7 and removed on March 11. Temperature rose to 39 degrees C but dropped promptly on removal of the maggots. The patient was discharged on March 12 and re-admitted on April 16 for the fifth and last introduction of maggots. On July 18, 19 months after the inception of the infection, she reported for observation completely healed.

On September 23 the patient re-entered the hospital for a brown induration of the axillary scar which had followed overexertion of that arm in a tennis game. An abscess broke spontaneously from which both the *Staphylococcus aureus* and the hemolytic streptococcus were recovered. Prompt healing occurred after evacuation of the abscess.

On January 16, 1933, the patient re-entered the hospital for an exactly similar reaction in the scar following heavy work in the garden. An abscess was incised which again yielded both *Staphylococcus aureus* and hemolytic streptococci. Complete healing followed, and no further trouble has developed.

An axillary abscess followed a small blister of the left hand which had been opened and exposed to animal fertilizer. In the original culture only the hemolytic streptococcus was recovered. After 11 months of progressive enlargement of the axillary wound and the development of a secondary ulceration of the chest wall, from which the hemolytic streptococcus and the *Staphylococcus aureus* were recovered, the wounds were treated by the introduction of maggots on 5 occasions in a period of 4 months. Healing was not complete until 19 months after the initial lesion had occurred.

On two subsequent occasions 2 and 6 months after complete healing had occurred,

Fig 3 a September 3 1932 Progressive ulceration of abdominal wall following simple appendectomy 10 months previously Note undermining of vulva b April 26, 1933. Re-epithelialization of abdomen by successive skin grafting following cantery debridement Granulating areas still present in both inguinal regions involving femoral vessels. x Site of erosion of left femoral artery y Site of incision for ligation of external iliac artery on April 3 1933

the trauma of effort initiated an abscess in the healed scar, from which organisms were obtained exactly similar to those presumably responsible for the initial lesion. In spite of the presence of both these organisms healing occurred without delay following evacuation of the abscess.

CASE 2: M W aged 42, housewife was operated upon February 6 1931 for a fixed pelvic mass, which was found to be an ectopic kidney. An appendectomy was performed through a lower midline incision. This incision broke down the edges became undermined, and despite numerous and varied forms of treatment, a gradually increasing ulceration of the abdominal wall developed. This treatment included irrigation with hypertonic salt solution, Dakin's solution, hydrogen peroxide, mercurchrome, the administration of potassium iodide and salvarsan, the use of the quartz lamp sun baths, a staphylococcus-streptococcus bacteriophage maggots in the wound, transfusion from an immunized donor and a high vitamin diet.

On December 30 an incomplete canterization of the wound with excision of overhanging edges of skin was performed and again on February 5 1932. Gradual extension of the ulceration occurred however until the patient was admitted to the Stanford Hospital on September 2 1933 17 months after a simple appendectomy and the inception of the infection.

On admission, the patient looked drawn and pale. She was exceedingly apprehensive and fearful of what would be done to her very painful wound. Her temperature was 38.5 pulse 120 respiration 22

hemoglobin 50 per cent red cells 2,500,000 white cells 15,550 polynuclears 82 per cent (47 per cent banded, 35 per cent segmented) lymphocytes 12 per cent, large mononuclears 4 per cent eosinophiles 1 per cent blood pressure 98/68 urine normal weight 92 pounds, average weight 142 pounds.

The condition of the abdominal wall is shown in Figure 3. The actual wound measured 23 by 17 centimeters, but the edges on all sides were under

Fig 4 CASE 2 August 16 1934 a, Appearance of wound 3 1/4 years after inception of infection. Note increased involvement of both inguinal regions, resulting finally in a fatal hemorrhage from the right femoral artery b, Progressive ulceration of left lower leg following abscess of heel due to infected arterial embolus incident to ligation of left femoral artery

Fig 5 a, September 6 1933 Appearance of ulceral wound 7 months following evacuation of abscess secondary to abrasion of finger b Appearance of secondary lesion above showing the characteristic appearance of edematous granulation tissue in center and undermining, discoloration, and necrosis of skin edges

mured for 4 to 6 centimeters. The flap of skin and subcutaneous tissue overlying the undermining was in certain areas 2 centimeters thick. The undermining process extended well under the labia.

A blood culture was negative. The cultures of the wound showed the presence of *Staphylococcus aureus*, hemolytic streptococci (beta Brown) and partially hemolytic streptococci (alpha prime Brown). Cultures from beneath the undermined skin on specially prepared media established the absence of anaerobes and fungi.

On September 9 1933 an extensive cautery débridement of the wound was performed by excising all areas of overhanging skin. The labia were almost entirely removed. The surface of the wound was lightly touched with the hot cautery. A disheartening feature was the extension of the infection into the region of the femoral vessels in both groins, thus preventing cauterization of the wound in these areas. A transfusion was given at the end of the operation.

On September 13 the red cells numbered 4,280,000 haemoglobin 53 per cent white cells 12,000 82 per cent polymorphs (70 banded, 12 segmented). On September 20 the white cells numbered 9,100, polymorphs 64 per cent (banded 17 per cent, segmented 47 per cent). Under saline and Dakin's irrigations, the wound improved, and on October 4 the first skin grafting was performed, 82 small deep grafts being applied to the granulation surface. On October 25 131 more grafts were applied, and on November 5 93 more were applied.

A high fever for 3 days on December 19 to 22 led to a blood culture which was positive for *Staphylococcus albus*. A blood culture in a week a time again yielded the same organism. The fever then subsided. A transfusion was performed on January 4, 1933 from an immunized donor. More skin grafts were applied on January 15.

By February 16 the abdomen was epithelized, but there was considerable undermining of the skin of the left thigh extending down from a sinus tract immediately over the left femoral vessels. This overhanging undermined skin was excised on February 16 followed on March 7 by skin grafting.

On March 27 began a series of episodes which eventually led to death 135 years later. Within 3 days several massive hemorrhages occurred from an aneurysmal erosion of the left femoral artery. On April 1 a transfusion was given. On April 3 the left external iliac artery was ligated through a clean area above the left superior iliac spine, following which all bleeding ceased. A transfusion was given at the end of the operation. April 13 transfusion April 26 transfusion May 3 transfusion. On May 4 the haemoglobin was 76 per cent.

On May 21 though not completely well, the patient returned home at her own request. Small discharging wounds were still present in both groins over the femoral vessels. The patient was instructed to take baths in hypertonic salt and in the sun.

In August all teeth were removed for multiple abscesses.

The patient was re-admitted December 16 1933 for excision of undermined skin surrounding many sinuses in the left inguinal region. The red cells numbered 4,000,000 haemoglobin 85 per cent white cells 20,220 79 per cent polymorphs (73 per cent banded, 6 per cent segmented). Cultures at this time yielded the *Staphylococcus aureus*, a diptheroid bacillus, the *Bacillus subtilis*, and the hemolytic streptococcus. On December 27 maggots were introduced into both inguinal wounds, but for some reason they refused to remain in the wounds. The pabulum was apparently not to their taste. On January 26 repeated massive hemorrhages from the site of the former erosion of the left inguinal artery necessitated ligation of the artery and division between ligatures. Cultures at this time showed a growth of *Staphylococcus aureus*, hemolytic streptococcus (beta Brown) and *Bacillus pyocyaneus*. Unfortunately the ligation of the artery had to be done in a pus soaked field and immediately after

the operation the patient complained of a painful heel. On March 21, 2 months later a small abscess was opened on the heel which was apparently precipitated by an infected arterial embolus at the time of the above ligation. Cultures from this secondary abscess showed a growth of the hemolytic streptococcus only. The entire left leg was greatly swollen and showed a marked glossy edema over the thigh leg and foot. April 14, 1934 transfusion. On May 18 excision of undermined skin and sloughing Achilles tendon on left was performed. The left foot was practically useless.

On June 4 the red cells numbered 4,600,000 hemoglobin 38 per cent and white cells 12,000. 86 per cent polynuclears (10 per cent banded, 76 per cent segmented) 12 per cent lymphocytes.

On June 6 excision of the undermined skin of the left calf and of the advancing necrosis of the Achilles tendon was repeated. July 3 further excision of undermined skin of the left calf. It had now reached the knee along the intermuscular septa.

On July 8 a massive hemorrhage occurred from the right femoral artery which was temporarily controlled by pressure. On July 31 another exsanguinating hemorrhage necessitated the ligation and division of the right femoral artery and vein. Transfusions were performed on August 2, August 6 and August 10. On August 12 a markedly firm edematous swelling of both thighs and legs developed (Fig. 4). Death occurred on August 17, 3½ years after the beginning of the infection.

In spite of heroic efforts to control an infection which began in an abdominal wound following a simple appendectomy, no headway was ever made in the region where the infection had invaded the inguinal glands and vessels. A bacterial destruction of the left femoral artery resulted in exsanguinating hemorrhages for which the left external iliac artery was ligated. Months later the same vessel again burst forth with terrifying hemorrhages for which the femoral artery itself was ligated and divided at the site of bleeding. Severe massive hemorrhages from an eroded right femoral artery finally resulted in death.

Although the hemolytic streptococcus and the Staphylococcus aureus were always recovered from the original wound only the streptococcus was recovered from the abscess initiated in the left foot by an infected arterial embolus following ligation of the left femoral artery in a pus-soaked field. This secondary lesion spread slowly but insidiously up the leg, with gradual undermining of the skin and involvement of the underlying Achilles tendon and calf muscles.

Fig. 6. a, September 30, 1933. Appearance of axillary wound showing its great depth following cautery débridement and introduction of maggots. b, Appearance of lesion on elbow following wide excision of its undermined areas, 23 days previously.

The case provided certain very striking lessons: first the need of early recognition of the irreastible character of the infection if not properly treated, and second, the need of

Fig. 9. a, Case 4. Phagedenic ulceration of thigh of a weeks' duration following careless picking of small pustule. Patient was a plumber. Healing after 5 months. b, Excised specimen consisting of base and overhanging edges of ulcerated skin.

excellent functional result. Contractures in the axilla were minimal in spite of a wide spread and deep-seated infection due it is believed to the control of infection without fibrous reaction through the use of maggots. Until healed the wound on repeated occasions yielded the 2 organisms, the hemolytic streptococcus and the *Staphylococcus aureus*.

CASE 4. C P J, aged 48 plumber considered himself perfectly well until 3 weeks before admission to Stanford Hospital on July 25, 1934, when he had picked a small pustule on the inner side of his left thigh with an ordinary pin. No dressing was applied, and within a day a sore swollen area developed, followed in another day by ulceration, which has spread rapidly since. The ulcer has been very painful and has discharged considerable pus. Ten days

after the onset the glands in the left groin became swollen and painful.

The patient's occupation as a plumber necessitated contact with sewage and the frequent wearing of rather dirty sewage-soiled trousers.

On admission the examination was negative except for a dirty ulcer on the inner surface of the left thigh about 3 by 6 by 0.5 centimeters in size, the edges of which were undermined and of an angriously bluish red appearance. Redness and induration extended beyond the edge on all sides for about 1 to 2 centimeters (Fig. 9). A tender mass of glands was easily palpable in the left groin.

The blood pressure was 160 systolic, 90 diastolic; the red cells numbered 4,800,000, the white cells 8,800, with 78 per cent polynuclears and 20 per cent lymphocytes, hemoglobin 86 per cent, urine, normal Wassermann reaction, negative. A culture from beneath the undermined edge showed hemolytic streptococci of the beta Brown type and a few colonies of *Staphylococcus aureus*. Anaerobic cultures established the absence of anaerobes. The basal metabolic rate on July 27 was minus 23 per cent. The blood sugar was 107 milligrams per 100 cubic centimeters.

On July 28 the entire ulcer including the overhanging edges and the dirty base, was excised with a radio cauterizer (Fig. 9). The microscopic section revealed only chronic inflammatory tissue.

Following debridement of the wound, 25 small deep grafts were applied to the clean looking ulcerated surface on August 9. Only four took, and these later sloughed off. Also on August 16 31 additional grafts were applied, but again all but seven were floated off in a sea of pus.

In spite of the administration of 2 grains of thyro daily the basal metabolic rate on August 25 was minus 25 per cent.

Under active debridement, the wound gradually cleared and the patient was discharged September 3 with the edges slowly growing in. By September 25 complete healing had taken place.

The important points of interest in connection with this case are (1) the occupation of the patient which requires contact with sewage (2) the presence of both the streptococcus and the staphylococcus in the wound though neither was anaerobic in character (3) the low basal metabolic rate (4) the slow but steady healing that occurred following cautery debridement of the ulcer which had given promise of being an insidiously progressive lesion.

EXPERIMENTAL DATA

Two dogs were injected with organisms obtained from Case 2. The hemolytic streptococcus was injected subcutaneously in the left flank, the *Staphylococcus aureus* in the

right flank, and an emulsive mixture of the two at the xiphisternum. In each instance a definitely more pronounced reaction occurred at the xiphisternum than in the flanks, with central sloughing at the site of injection over a very limited area. Prompt healing followed the spontaneous evacuation at the site of sloughing of a small amount of thin pus.

In a third dog a remarkable gangrene of the skin and muscles of the chest wall occurred, causing the death of the animal in 3 days, but cultures of the pus revealed, in addition to the streptococcus and staphylococcus, the presence of Welch's bacillus.

In 2 other animals the *Staphylococcus aureus* obtained from Case 4 was injected first, causing a mild reaction. At the height of reaction, the hæmolytic streptococcus obtained from the same case was injected at the same site. The reverse order was attempted in another animal but in each instance no gangrene nor spreading infection occurred.

A sixth animal was similarly injected with the organisms recovered from Case 3 namely an aerobic streptococcus and an anaerobic staphylococcus, without producing any lesions other than small abscesses which healed promptly.

DISCUSSION

Four cases are presented, exhibiting the characteristic features of the progressive and relentless bacterial ulceration of the skin and subcutaneous tissues described in the literature most commonly as a complication following operation for a ruptured appendix. In reviewing the recorded cases one cannot escape the inference that some intestinal organism or organisms are in some way responsible for these remarkable infections. In the 4 cases reported here, 1 followed an appendectomy, 2 followed the draining of axillary abscesses secondary to lesions of the hand—1 incurred while handling animal fertilizer, the other incurred while grating carrots, a product of the field, and the fourth occurred in a plumber whose clothes were habitually soiled by sewage.

Meleney's cases have invariably yielded in culture a non hæmolytic, micro-aerophilic streptococcus, which together with the *Staphylococcus aureus* he considers specific for

this type of infection, and his hypothesis that it is due to a bacterial synergism, a symbiotic phenomenon involving the two organisms, has found ready acceptance. Little corroborative evidence is to be found in the recorded cases due to lack of uniformity in the bacteriological studies made, and due to the great variety of organisms recovered from the lesions. In the cases here presented two organisms were invariably found, but the streptococcus recovered was hæmolytic and aerobic.

Moreover, in the recorded cases Christopher, Cullen Shipley, Poate Ballin and Morse, Carol and Horsley report the recovery of only the hæmolytic streptococcus from the wounds of their patients, and in two instances—Luckett, and Prohstein and Seelig—only the staphylococcus was recovered. Of more than usual interest in a group of patients reported by Stookey, Ferns et al., who observed as a complication of erysipelas the development of necrotizing ulcers, from which a pure culture of *staphylococcus aureus* was obtained. The necrotizing factor they attributed to a bacteria free filtrate presumably an exotoxin, recovered from cultures of this staphylococcus. When this filtrate was injected intracutaneously into the skin of a rabbit, necrosis invariably occurred, although filtrates from the *Streptococcus erysipelas* and from a *Staphylococcus aureus* recovered from a furuncle, yielded no such necrotizing element. The authors postulate a specific staphylococcus possessing dermonecrotic properties.

Our animal experiments with attempts to reproduce the lesion by inoculation of two organisms singly and in combination, corroborate Meleney's observation that two organisms together produce more pronounced lesions than single organisms, but in no instance were we, or Meleney, able to reproduce the progressive lesion seen in the human cases.

Experiences such as these almost force one into that mysterious wilderness of medical knowledge, the realm of individual resistance to infection and the highly enigmatical state of virulence of the infecting organisms which may exhibit extraordinary and highly individualistic qualities under different conditions.

TABLE I.—RECORDED CASES OF PROGRESSIVE ULCERATION

Author	Patient Sex Age	Source	Duration	Organisms recovered	Treatment
Lockett 909	M 33 (German)	Parastoma of abdomen	3 weeks	<i>Staphylococcus aureus</i>	Curettage
Christopher 914	M 44	Empyema (lung abscess)	33 days	<i>Anaerobic streptococcus</i> <i>Bacillus coli</i> Green fermenting strept.	Curettage Tracheostomy

In our fourth case, efforts to study the factor of individual resistance resulted in an unusual finding. The patient on two occasions showed a basal metabolic rate of minus 23 and minus 25 per cent. Case 3, when on the road to recovery, however, showed a normal metabolic rate of plus 7 per cent. No deductions may be made on the evidence available.

In treating such infections every effort should be made to increase the resistance of the host to infection. This may be accomplished by transfusions, by sun baths and by a high vitamin diet augmented by cod liver oil and vitamin B. The case of Probst and Seelig responded promptly and decisively to blood transfusion from immunized donors.

Locally, the resistance of the host to the infecting organisms was affected in our axillary abscesses by the introduction of maggots which, according to Baer's unique and highly original observations remove, by ingestion, necrotic and near necrotic tissue, and change the hydrogen ion concentration of wound secretions toward the alkaline side—two factors destined to reduce the propagation of the infecting organisms by rendering the local conditions unfavorable.

In adopting maggot therapy, two precautions must be observed: (1) Adequate medication, such as morphine, pantopon, or sodium amytal, should be employed every 2 hours to control pain. (2) Maggots must be used in sufficient number so that every part of the wound is being attacked simultaneously.

The success of the débridement lies in carrying the incision boldly and courageously through absolutely healthy skin and subcutaneous tissues, and abolishing all pockets where pus may accumulate and stagnate. There must be no hedging in this procedure; all overhanging tissue must be removed. It is possible that pools or pockets of pus exhaust the defensive mechanisms of the body and once these pockets are removed, the defensive forces may gain the ascendancy. In this connection it is interesting to note the reaction of the polymorphonuclears to the extensive infection in Case 2. On the patient's first admission, in the presence of an advanced infection the white cells numbered 15,550. 82 per cent polynuclears, 47 per cent banded and 35

per cent segmented. Eleven days later, 4 days after an extensive débridement, the white cells numbered 12,000. 82 per cent polynuclears, 70 per cent banded, 12 per cent segmented. Thirteen days later, when the suppuration was under much better control, the white cells numbered 9,100. 64 per cent polynuclears, 17 per cent banded, 47 per cent segmented.

On the second admission, again in the presence of marked suppuration, the white cells numbered 20,120. 79 per cent polynuclears, 73 per cent banded, 6 per cent segmented. On June 4, still in the presence of widespread suppuration, the white cells numbered 12,000. 86 per cent polynuclears, 10 per cent banded, and 76 per cent segmented. Death occurred on August 17. On the first admission, the observations might have been considered significant; the later studies were contradictory.

It seems very unlikely, from the fatal outcome in Case 2, that the deep-seated axillary abscesses in Cases 1 and 3 could have been successfully treated without recourse to maggot therapy. Complete cautery débridement and the abolition of all pockets was obviously impossible. Only maggots could cope with the dirty oedematous granulation tissue, containing numerous organisms, which extended in each instance to the very apex of the axilla. One unexpected advantage resulting from the maggot therapy was the kindly healing that occurred in both axillary abscesses without permanent cicatricial contractures. Full range of motion is now present in both of the patients with deep axillary abscesses recorded here; attributable it is believed to maggot therapy. In treating axillary abscesses it is important to support the arm in the abducted position by means of the Balkan frame.

SUMMARY

Four cases of progressive bacterial ulceration of skin and subcutaneous tissue are presented, one cured by maggot therapy alone, one by cautery débridement and maggot therapy, and one by cautery débridement alone. A fourth case succumbed following repeated massive hemorrhages from eroded femoral arteries, in spite of repeated débridements, which were ineffectual due to the involvement of the femoral sheath.

Discussion

DR EDWARD D. CHURCHILL, Boston When a scientist asks for a frog to use for a crucial experiment he expects to be given a frog and not an animal that may be a frog. To obtain consistent bacteriological findings to support a theory as to the causative agent of a disease, the clinician must first of all be certain that his cases are all examples of a single disease entity. There is real difficulty ahead in attempting to assign a specific etiological agent to a variable and protean disease as chronic progressive superficial ulceration. Although our bacteriological technique may be exact, we start with an incorrect clinical diagnosis. These ulcerations that Dr Holman has described have many manifestations that are the same as those seen in a group we have studied at the Massachusetts General Hospital. The cases correspond to Dr Mileczyk's group and to many other cases reported in the literature but the clinical identity may well not check with the bacteriological identity. We have found by animal inoculation that the microaerophilic streptococcus and staphylococcus recovered from many of these ulcers do appear to represent the disease more nearly when injected as a mixed culture than when injected singly. However the confusion in nomenclature rests as much on clinical findings as on bacteriological analysis.

Fortunately the proper treatment may be carried out irrespective of these uncertainties as to etiology.

The prompt recognition by surgeons of the fact that superficial ulcerations anywhere upon the body may be relentless in their progression and fail to respond to any of the usual surgical methods of control is important. If they are correctly treated at an early stage, months or years of invalidism or a final fatal termination may be prevented.

I have found personally that an excision of the margins of these ulcers with the electrocautery knife followed by skin grafting is the most effective method of control. It is only effective, however if the ulceration is still so limited that it may be excised. I have lost a case that extended into the peritoneum and the femoral sheath. I have lost a second case that started as a simple breast abscess but at the time the condition was recognized involved over one-half of the entire chest and abdominal wall and was complicated by sinuses extending under ribs that had previously been resected. We have cured at least 7 patients in whom the lesion, although extensive in some instances, could be radically excised.

I believe that the ulcer Dr Holman has described is essentially a disease of the subcutaneous tissue and that its manifestations vary in different portions of the body depending upon the thickness of this layer. The skin melts away following the destruction of its blood supply through the undermining infection. In abdominal cases the umbilicus is usually left at

the apex of a peninsula because of the lack of subcutaneous fat beneath it. On the dorsum of the hand the skin may actually gain a new blood supply and remain viable in the center as the active process extends peripherally.

A very important aspect of these cases that Dr Holman has stressed is the mental attitude of the patient. Many of them have been treated by a series of doctors, each one of whom promises relief at the outset only to find himself faced with defeat after the unsuccessful use of one or more new methods of treatment. The exquisite pain of repeated surgical dressings breaks the morale of the most phlegmatic individual. Most of these patients accept further treatment with reluctance or with a complete lack of confidence. I recall vividly one patient who had

been treated for a year with sunlight therapy under a diagnosis of tuberculosis suggested by the coincidence that the ulceration followed the removal of a tuberculous pyosalpinx. During this year the patient watched the steady progression of the ulcer until it extended from above the umbilicus to the pubes and from one iliac crest to the other. To gain the confidence of this patient it was necessary to delay operative procedures for 3 weeks and build up her morale by occupational therapy and psychiatric consultation. Even when completely healed this individual was forced to spend over a year in a mental institution to recover from the effects of the disease. Surgeons must recognize the true nature of these ulcerations at an early date if such serious complications are to be avoided.

SOME REMARKS ON THE GIANT CELL TUMOR OF BONE¹

HARRY PLATT M.D. M.S. F.R.C.S. F.A.C.S. MANCHESTER, ENGLAND

Honorary Orthopaedic Surgeon, Royal Infirmary, Manchester; Lecturer in Orthopaedic Surgery, University of Manchester

THE tumor known under the various titles of giant cell tumor, myeloid sarcoma, or osteoclastoma, is somewhat of a clinical enigma to the practical surgeon of today. There are three main reasons for this state of uncertainty: (1) the tumor can no longer be regarded as a histological entity—a fact which has an important bearing on the problems of diagnosis and treatment; (2) the tumor is rare and its clinical behavior variable; and (3) in the treatment of the tumor there appears to be a tendency to substitute some form of irradiation for early surgical intervention.

THE IDENTITY OF THE GIANT CELL TUMOR

To the surgical generation which immediately succeeded Paget (1853) and Nélaton (1860) the myeloid sarcoma, as it was then usually called, appeared securely established as a clinical and histological entity. It was sufficient merely to emphasize the distinctions between it and the true sarcoma of bone. Until the advent of von Recklinghausen's classical description of generalized osteitis fibrosa (1891) this conception remained unchallenged. But with the ultimate widespread recognition in more recent years, that typical osteoclastomata can almost invariably be found in the varied histological pattern which characterizes the osteitis fibrosa group of lesions, the separate identity of the giant cell tumor is now by no means so obvious. For here is the seeming paradox of a histological picture shared by two lesions generically opposed on the one hand—a true tumor of bone—an osteoclastoma—which behaves in every particular as a neoplasm, and, on the other—a dystrophy of bone—admittedly non-neoplastic, which exhibits a striking tendency toward spontaneous healing. For the moment we are concerned only with one clinical type of osteitis fibrosa—the solitary bone cyst.

The outstanding differences between the clinical picture of the bone cyst in children and the giant cell tumor in the adult are fa-

miliar to all surgeons. Some of the main points relating to age and sex incidence, skeletal distribution, site of origin, and clinical course are conveniently summarized in Table I.

TABLE I

	Solitary bone cyst		Giant cell tumor	
Age	5-45 (major 20)		20-35 (major 30)	
Sex	M > F		F > M	
Site of Election	Humerus Femur	Upper end Transverse region Tibia Upper end	Femur Tibia Radius	Lower end Upper end Lower end
Site of origin	Metaphyseal		Epiphyseal	
Clinical course	Trauma → Fracture Spontaneous healing +++		(Trauma) → Trauma → Tumor Incurable and destructive	

Geschickter and Copeland (9) for whose work on this subject I have the greatest admiration, believe the average bone cyst to be a giant cell tumor which has either already healed or is in process of healing. These authors also recognize as histological entities (a) a giant cell variant of osteitis fibrosa, and (b) a spindle cell variant of the giant cell tumor. These hybrid lesions, which have been described by Geschickter and Copeland more especially in the cysts of the miniature long bones, form a connecting link between the cyst at one end of the scale and the giant cell tumor at the other.

I would urge that the significance of the histological kinship between the cyst and the giant cell tumor be not unduly stressed. There is a danger that this fascinating argument if carried too far may tend to disturb the clinician's sense of perspective and lead not only to hesitancy in diagnosis, but—most important of all—to delay and imprecision in the treatment of the giant cell tumor. It is far wiser in my judgment, that we should continue to emphasize the complete independence, as clinical and pathological entities, of the two lesions under consideration. By so doing we are able to formulate principles which will determine the rational treatment of the giant cell tumor. For whereas a cyst may often be treated at leisure by conservative methods, I

am of the opinion that, with certain exceptions, a giant cell tumor should without delay be eradicated by appropriate surgical measures.

Despite the underlying histological unity between the two lesions, when compared with the typical bone cyst the ordinary giant cell tumor is quite obviously a definitive clinical entity. But solitary cystic lesions of bone from time to time present themselves, which do not conform exactly to type and which, at first sight, might be legitimately mistaken for giant cell tumors. These are cysts exhibiting rapid growth with perforation of the bone shell, after the manner of a true tumor and generally occurring in young adults. Such cysts may contain liquid blood in addition to clumps of tumor like tissue of varying consistency and hue. In the absence of a definite fibrous lining to the cyst wall this tissue is not easily distinguishable, on naked eye appearances, from true giant cell tumor material in older individuals. The two following cases from my own collection illustrate some of the uncertainties which may arise in this connection.

CASE 1. Female, aged 15 years. Cyst of pubis, left.

The symptoms, pain in left groin and intermittent lump, had been present 3 months. There was no trauma.

Examination revealed a swelling along the brim of the pelvis on the left side.

X ray examination showed expansion of the body of the pubis and pubic ramus on the left side with partial disappearance of the ramus (Fig. 1).

Operation consisting of curettage and cauterization of the cyst was done October 29, 1923. The bony shell had largely disappeared but an intact fibrous capsule was discovered which formed the wall of a large cyst containing liquid blood and masses of tumor like tissue. *Severe hemorrhage was experienced*, which necessitated temporary packing. The contents of the cavity were evacuated and the interior cauterized with pure carbolic acid.

Histological examination revealed an active cellular picture, consisting of round and spindle cells with well marked giant cell areas. giant cells scanty but large with many nuclei. areas of osteoid bone and hemorrhages.

Result. Complete obliteration of the cyst with reformation of pubic ramus (Fig. 2).

A rapidly growing cyst of the osteitis fibrosa group in an unusual site and containing liquid blood and tumor like tissue was suggestive of

the naked eye of a giant cell tumor. The lesion showed well marked invasive qualities but was cured by curettage and cauterization.

CASE 2. Female aged 23 years. Cyst of femur lower end, left.

The symptoms were of 9 months duration and consisted of pain in the left knee followed by the appearance of a lump on the inner side of the thigh which rapidly increased in size. no trauma, severity of pain a striking symptom.

Examination revealed a localized bony expansion of the left femur just above the inner condyle, tender on deep pressure.

X ray examination disclosed an eccentric multicystic expansion involving the lower part of the shaft of the femur immediately above the inner condyle. The site of origin was the *metaphysis*. the bony shell was attenuated on the superficial aspect and absent in places (Fig. 3).

Operation on December 11, 1931, amputation was done through the middle third of the thigh.

Description of specimen. The cyst was almost completely empty except for the presence of a small amount of clear fluid, the interior was lined with patches of tissue, lightly adherent to the bony shell. this tissue in places was tough and fibrous but over the greater part of the cyst wall was friable and presented the maroon color of a giant cell tumor.

Histological examination of the cyst lining revealed a fibrous tissue and spindle cell background containing typical giant cell tumor areas, the giant cells were in moderate numbers, large, and contained many nuclei (Fig. 4).

Result. Three years later, the patient is well wearing an artificial limb and following her occupation.

This is also to be regarded as an atypical bone cyst of the osteitis fibrosa group. True to type, the lesion originated in the *metaphysis* but was eccentrically placed, after the manner of a giant cell tumor of the epiphysis. The age of the patient, the rapidity of growth and the radiographic appearances, are also reminiscent of giant cell tumor. Owing to the size, position, and rapid growth of the cyst, it was considered unsuitable for treatment by curettage. Local resection was also rejected as involving a mutilating operation with a long postoperative period of disability. The patient herself was anxious to return to her occupation at the earliest moment and eagerly concurred in the suggestion of amputation.

I believe that a cyst which runs an atypical course—as in the examples quoted above—like the proverbial leopard, does not really "change its spots." Such cysts are neither

hybrids nor atypical giant cell tumors. It seems logical to look upon them as true bred cysts of the osteitis fibrosa group in which an unusually active tissue proliferation has resulted in bone destruction. Indeed the problem of the rapidly growing cyst in the adult has even wider implications. For it is well known that benign cysts eccentrically placed at the end of a long bone, and packed with actively proliferating spindle cell tissue, have not infrequently been diagnosed as sarcomata and treated by amputation of the limb! We may therefore conclude that the occasional tendency of a bone cyst to run amuck and assume tumor like activities, does nothing to invalidate the position of the giant cell tumor as a neoplasm *sui generis* and as an independent clinical entity.

CLINICAL ATTRIBUTES OF THE TUMOR

One of the most striking facts about the giant cell tumor of bone is its undoubted rarity (I am excluding for the moment the common periosteal *spulis* of the jaw which lies outside the clinical problems under consideration). It has been estimated that the average yearly quota of giant-cell tumors of the long bones in the larger general hospitals of Great Britain, is not more than one tumor per year per hospital (Stewart, 6). It is evident that the majority of hospital surgeons do not enjoy a continuity of experience which enables them on every occasion to deal authoritatively with a tumor which makes so infrequent an appearance. In this generation however the surgical profession has the inestimable advantage of being able to turn to the wealth of knowledge made available by the intensive study of bone tumors on an unprecedented scale in the United States of America. Every surgeon who is continuously interested in this problem, must feel impelled to voice his lasting indebtedness to four great pioneers in this effort: J. C. Bloodgood, E. A. Codman, W. B. Colcy and J. S. Ewing.

A contemplation of the giant cell tumor in its various guises would seem to warrant a recognition of three clinical types—(1) the indolent, slowly growing tumor, (2) the active, rapidly growing tumor and (3) the rare, malignant tumor. At the same time one cannot

escape the impression that no two tumors behave alike.

1 *The indolent tumor* The indolent tumor is characterized by a very slow rate of bony expansion over a considerable period of time. Its relatively feeble invasive and destructive qualities are made manifest (a) in the roentgenographic picture of a thick bony wall and coarse trabeculation and (b) in the histological picture by the presence of considerable areas of fibrous tissue. This histological type of giant cell tumor was well known to the older pathologists, who regarded the fibrous tissue reaction as an attempt on the part of the tumor to undergo spontaneous healing (Ribbert).

Indolent tumors have formed a very small proportion of my own series of giant cell tumors and as it happens, they have all been growths of the lower end of the femur in individuals under 30. I do not attach any importance to the question of site, but I believe the age factor is significant and that slowly growing tumors endowed with very feeble powers of invasion are exceptional after the age of 35.

2 *The active tumor* The active, more rapidly growing tumor showing well marked invasive and destructive qualities seems to represent the giant cell tumor in its true colors. The clinical picture is a familiar one. With symptoms of comparatively recent origin, the tumor is already appreciable on clinical examination and is known to be steadily increasing in size. The bony shell, as depicted in the roentgenograms, is attenuated and already perforated at one or more points. The microscopic picture is characterized by a profusion of giant cells, embedded in a background of actively growing cells, both of the round and spindle type.

The active type of giant cell tumor is met with in the young adult as well as in individuals approaching middle age or even later and its behavior does not appear to be determined by its selection of site. The more one has to do with the giant cell tumor the more one is impressed by its invasive and destructive qualities, especially in individuals over 30. It is because of such activities that I am accustomed, when teaching students, to refer to

Fig. 1. Case 1. Cyst of pubis (osteitis fibrosa) in a girl aged 15. A cystic expansion of body and ramus of pubis on left side with considerable destruction of bony shell.

Fig. 2. Case 1. The roentgenogram shows reformation of the pubic ramus 4 years after the operation of curettage and cauterization.

the tumor as a *malicious* although not a malignant neoplasm. I have probably been influenced by the fact that more than half of the cases in my own series have been patients in the fourth or even fifth decade of life. Indeed, the surprising incidence of this tumor in the middle aged occasionally leads to difficulties in the differential diagnosis of solitary secondary malignant tumors of the long bones, where the primary growth is latent.

The inherent aggressiveness of the typical giant cell tumor is convincingly demonstrated in its tendency to recur locally after operations which, at the time, may have appeared sufficiently radical. The following case from my own collection is instructive in this respect.

CASE 3. Female aged 23. Giant cell tumor of head of femur right.

The patient had had pain and a limp for 6 months. Examination disclosed the clinical picture of a subacute arthritis of the right hip joint.

X-ray examination revealed a faintly trabeculated cyst, occupying the lower half of the femoral head and extending into the lower border of the neck bony shell almost disappeared (Fig. 5).

The first operation was done December 18, 1931, at which time the hip joint was explored and the head and neck of the femur resected.

When the hip joint was opened and the femoral head inspected, a localized bulge of encapsulated tumor material was noted at the junction of the lower border of the head and neck. The femoral head was flattened and triangular in shape and showed a perforation of the articular cartilage in the region of the attachment of the ligamentum teres. Through this

perforation a tiny clump of tumor tissue was on the point of escaping. An effective curettage and cauterization operation was regarded as impracticable. Accordingly the femoral head and neck were excised *en masse*, the neck being divided well beyond the presumed margins of the tumor. The stump of the upper end of the femur was cauterized with carbolic acid in the usual way. During the operation a rapid smear (Dudgton technique) of the tissue protruding through the hole in the articular surface of the femoral head showed the characteristic cells of a benign giant cell tumor.

Description of specimen. About one half of the interior of the femoral head was occupied by a multilocular cystic area containing reddish brown tissue with "red-currant" areas. There was a perforation of the articular surface in the region of the ligamentum teres attachment (Fig. 6).

Histological examination of contents disclosed a typical benign giant cell tumor with giant cells in great profusion. (Fig. 6).

As it was believed that a clean sweep had been made of the tumor it seemed reasonable to attempt to stabilize the hip joint at an early date. Some 2 months after the excision of the tumor a second operation was performed (February 15, 1932) and included a reconstruction of the head of the femur by a homogenous graft. The astragalus removed from a patient of a similar blood group with a long standing ununited fracture of the leg bones, was attached to the upper end of the femoral shaft (Fig. 7). There was no naked eye evidence of recurrence of the tumor. Four months later the patient was fitted with a walking caliper. The hip joint was surprisingly stable and allowed a short range of movement. Six months from the time of the operation a roentgenographic examination showed a cystic change in the upper part of the shaft, suggesting recurrence of the tumor (Fig. 8). There was no clinical evidence to support this conclusion. The patient was unwilling

Fig. 3. Case 2. Cyst of femur (osteitis fibrosa) in a female aged 25. A large cyst arising eccentrically in the metaphysis showing marked thinning of the bony shell on the superficial aspect.

to give consent for further operation and, therefore, a course of deep X-ray therapy was advised. Valuable time was lost before arrangements could be made for this treatment. In the meantime the cystic area had steadily increased in size (Fig. 9). After the course of deep therapy the hip remained very painful, there was an increasing swelling of the soft parts, and the joint became completely fixed. A further roentgenogram showed no shrinkage in the tumor area. The question of amputation was discussed but the patient consented only to a further local attempt to excise the tumor (Fig. 10).

A third operation consisting of re-exploration and excision of upper end of femur was done.

July 24, 1933 the dense fibrosis and adherence of the soft tissues to the bony shell and capsule of the tumor made the operation extremely difficult. As it was not felt certain that every particle of the bone shell and capsule had been eradicated, the operation wound was re-opened 15 days later and radium tubes, enclosed in a sorbo rubber pack, were inserted. Progress following the operation was most satisfactory and sound healing of the wound rapidly occurred. Two months later the patient began to bear weight on the limb in a caliper splint.

Results up to date. One year after the last operation, there is no clinical or radiographical evidence of recurrence in the upper end of the femur. There is

gross shortening of the limb but the patient is able to walk quite comfortably in the caliper splint (Fig. 11).

1. A giant cell tumor actively invasive and destructive, occurring in an unusual situation and treated by a radical excision of the tumor bearing area (head and neck of the femur). A re-exploration of the hip joint 2 months later for the purpose of insertion of a homogenous graft, afforded an opportunity of demonstrating the absence of naked eye evidence of local recurrence.

2. Unmistakable roentgenological signs of recurrence in the upper end of the femur were discovered 6 months from the time of the reconstructive operation and ultimately the homogenous graft (astragalus) was completely invaded by tumor.

3. The recurrent tumor which rapidly attained to a considerable size continued to grow in spite of irradiation (deep X-ray therapy).

4. The recurrent tumor was treated by excision and radium implantation.

5. The patient is still under observation and has remained free from signs of recurrence for a year from the date of the last operation.

I have recorded elsewhere a similar example of the recurrence of a giant cell tumor in a bone graft used to replace the metacarpal bone of a thumb after a previous excision of the original tumor (4).

3. *The malignant giant cell tumor.* The question of the potential or actual malignancy of the giant cell tumor has in the past excited considerable controversy. It is now generally admitted that on very rare occasions, the tumor may assume all the local and metastatic attributes of a true malignant neoplasm. Whether this phase of activity represents a superimposition of malignancy on a benign tumor (Geschickter and Copeland, 1) or—more probably—a true dedifferentiation of the specific cells of an osteoclastoma (Stewart, 7) still remains to be settled by the pathologist. It is the sequence of events in the clinical story of the true malignant giant cell tumor which concerns us at the moment—a tumor with a long career appearing in the first instance as a typical benign lesion between the ages of 30

Fig. 4. Case 2. Histology showing parts of a giant cell tumor area

and 40, and recurring locally on several occasions after curettage or even after local resection, and progressing to ultimate metastasis in spite of belated amputation. The lessons to the practical surgeon are obvious (1) the necessity for a truly radical removal of the tumor at the first attack, and (2) the desirability of being able to recognize the onset of malignancy in a neglected or recurrent tumor before the stage of dissemination.

In a recent contribution E. S. J. King of Melbourne, has described the histological and roentgenographic criteria on which a diagnosis of impending or actual malignancy may be made in atypical giant cell tumors. These in his opinion, are (1) a predominating spindle cell stroma with mitoses and tumor giant cells in addition to the typical benign giant cell areas in other parts of the tumor, and (2) loss of outline of the bony shell, irregular trabeculation, and the shadow of tumor material in the soft parts. King also challenges the well known dictum of Bloodgood that perforation of the bony shell is not necessarily a sign of malignancy. My own experience would tend to confirm the soundness of Bloodgood's teaching for I have cured by curettage and cauterization tumors in which the bony shell had almost disappeared. The fibrous capsule was however still intact. But even the ultimate perforation of the fibrous capsule and the invasion of the surrounding soft parts, are in

themselves no proof of malignant behavior although they obviously call for drastic excision of the tumor bearing area, or amputation.

Neglected tumors which fungate through the skin are fortunately an uncommon experience at the present day. I have had one example of this unusual clinical phenomenon in a tumor of the lower end of the fibula in a woman of 42 years with a comparatively short history and treated by a previous curettage. The histological picture was a typical benign osteoclastoma but no complete histological survey of the greater part of the tumor was made (Fig. 12). The patient was known to be alive and well 1 year after amputation but all efforts to trace her during the past 10 years have been unsuccessful.

So far it has not fallen to my lot to meet with an example of true malignancy in a giant cell tumor.

TREATMENT OF THE GIANT CELL TUMOR

It will be generally agreed that, in the treatment of the giant cell tumor, our aims should be the complete eradication of the tumor with the minimum amount of mutilation. It is, therefore, pertinent to ask how far surgical treatment, as a primary resort, fulfills these requirements. The rôle of three types of operation must be considered (1) curettage, (2) local excision, and (3) amputation.

SURGICAL MEASURES

1. *Curettage* The conservative operation of curettage and cauterization, which we owe to Bloodgood has, in recent years, fallen somewhat into disrepute. There can be no doubt that, in the past, this operation has been practiced indiscriminately by surgeons with little experience in its specialized technique, and ignorant of its limitations. In a large group of giant cell tumors from the American Bone Sarcoma Registry analyzed by Simmons (5) some years ago the cures following curettage were 62 per cent only. I believe however that, in carefully selected cases, curettage should continue to be an operation of choice. For the indolent tumors it is, of course, an ideal procedure but, as already suggested, these are likely to be in a minority. The crucial test of the operation is its effectiveness in the early stages of rapidly growing tumors of moderate size even after actual perforation of the bone shell has taken place (Fig 13). The technique of curettage is discussed too rarely and, in consequence, there is a belief that the operation is a minor procedure. The removal of every particle of tumor tissue from the interior of a large bone cyst, the control of the resulting hemorrhage and the final systematic chemical cauterization of the whole tumor cavity is a precise technical performance, demanding both judgment and experience. The operation has too often consisted of a hasty "scrape"

Fig. 9.

transplantation. State of the tumor after deep X-ray therapy treatment.

Fig. 11. Case 3. One year after treatment of recurrent tumor by excision combined with radium implantation.

and a perfunctory sponging of the bone cavity with carbolic acid. It is not surprising that many failures are on record.

The selection of curettage as the operation of choice should be determined, not only by the size and type of the tumor but by the anatomical situation. In regions where a local resection can be performed without undue mutilation, this procedure should be definitely preferred to curettage.

In certain tumors of the lower end of the femur and upper end of the tibia (the classical sites) where there would be no difficulty in eliminating all traces of tumor tissue the thickness of the barrier which separates the tumor from the cavity of the knee joint is the deciding factor. For during an efficient curettage there is a risk that a fragile shell may be cracked or perforated on its articular aspect.

The dangers of repeated curettage are now well appreciated. If local recurrence follows a primary curettage the second operation should be either resection or amputation according to the anatomical indications.

The effective scope of curettage has undoubtedly been extended by the use of post operative irradiation. In the tumors analyzed

by Simmons, the cures following the combination of curettage and irradiation were 72 per cent. My own experience of this technique though comparatively small, is encouraging. I have had one striking example of the value of radium implantation following incomplete curettage and chemical cauterization in a large hemorrhagic giant-cell tumor of the ilium which had burst through its bony shell. This was a tumor which, on the earlier histological findings was at first regarded as a true sarcoma (4). This patient is alive and well 10 years from the time of operation.

In tumors in certain less accessible situations curettage followed by repeated courses of deep X-ray therapy, is an admirable substitute for the more mutilating alternative of excision. I have one such case under observation at the present time—a giant cell tumor of the head and neck of the femur—which appears to be undergoing progressive healing (Figs. 14 and 15).

2. *Excision.* As an operation of the first instance, excision is chiefly applicable in tumors of the upper limb where excellent function may be preserved after resection of the ends of any of the major long bones, with the

Fig. 12 Giant cell tumor lower end of humeri in a female aged 42. Showing fungation of the tumor through the skin.

exception of the lower end of the radius (Figs. 16a and b). If it is considered advisable that the resulting loss of bone should be made good by the insertion of an antogenous graft, it is wise to postpone the reconstructive operation until it seems certain that local recurrence is unlikely (see Case 3).

In the lower limb there are few opportunities of practicing resection, except in tumors in unusual sites, such as the fibula or head of the femur for which curettage is considered to be impracticable.

Compared with curettage the operation of excision gives a much higher percentage of cures—in the series already referred to (Simmons)—the ideal figure of 100 per cent.

3 *Amputation*. Little need be said on the general subject of amputation in the treatment of giant cell tumors. In the lower limb the operation is inevitable in neglected tumors in the region of the knee which have progressed to the stage of advanced destruction with impending invasion of the knee joint, and in certain tumors which have recurred after curettage or have defied irradiation. In tumors of the lower end of the femur or upper end of the tibia, which can be cured only by curettage and cauterization at the expense of the integrity of the knee joint, the operation may be desirable at an early stage. In patients of middle age the economic advantages of amputation are considerable and the loss of a limb is a small price to pay for the elimination of a tumor which is obviously a menace to the patient's life.

PRIMARY IRRADIATION

It remains to consider whether there is any justification for the use of primary irradiation as a substitute for operation in tumors which are still amenable to conservative operative attack. In the uncommon giant cell tumors of the flat bones e.g. the ilium, where curettage may be of doubtful efficacy and complete excision impracticable irradiation is the only form of therapy available. But the deliberate choice of irradiation as a primary measure in tumors of the long bones is often, in my judgment a somewhat hazardous experiment. There is not only the obvious objection that, in the absence of histological evidence derived from a biopsy the diagnosis may remain in doubt. Still more important is the difficulty which arises in connection with the interpretation of the clinical, and more especially the radiographic, signs of healing in a tumor undergoing irradiation. The appearance in the roentgenograms of zones of bone sclerosis at the periphery of the tumor though suggestive of bone repair is not convincing proof of the death and obliteration of the tumor cells *en masse*. There is also the potential injurious effect of prolonged irradiation on articular cartilage to be reckoned with. If the penetration is sufficiently powerful to kill an osteoclastoma of the lower end of the femur or upper end of the tibia, the knee joint is bound to suffer. This objection applies equally to the use of irradiation after the operation of curettage. For this reason, as a general rule, the use of postoperative deep X-ray therapy should be

confined to tumors in situations such as the hip, where ankylosis may be far less disabling than the functional results of a resection of the upper end of the femur.

I believe that valuable time may be lost in waiting for a tumor to heal under irradiation. It is not sufficient for the radiologist to claim that the tumor is held in check over a long period. If irradiation is to compete on even terms with the conservative surgical procedures, there must be convincing evidence in a short period of time of shrinkage of the cyst and obliteration of the cavity by new bone without the clinical signs of deterioration of the joint in the neighborhood of the tumor. These points are illustrated in the following case of my own series.

CASE 4. Male, aged 56 years. Giant cell tumor of lower end of femur, right.

The patient suffered a contusion of the right knee followed by a localized cystic expansion of the external condyle of the femur. Operation was not advised and a trial of irradiation was suggested. Three courses were given over a period of 15 months. During the early stages the tumor was believed to be under control, but during the last 6 months the knee became steadily more swollen, more painful, and fixed.

On examination June 4, 1934, there was found a well marked enlargement of the external condyle of the femur with local tenderness, distended veins, the knee practically fixed in 15 degrees flexion, marked wasting of the thigh.

Fig. 14, left. Giant cell tumor head of femur in a female aged 17. Pre-operative X-ray.

Fig. 15. Giant cell tumor head of femur in a female aged 17. Eleven months after curettage and cauterization, followed by deep X-ray therapy. Appearance suggests obliteration of the tumor.

Fig. 13. An active, rapidly growing giant cell tumor of the lower end of the femur in a man of 30 with early perforation of the bony shell and treated by curettage and cauterization. Shows condition 5½ years from the time of the operation.

X-ray examination January 3, 1933, made after the original injury (Fig. 17) showed localized eccentric cystic expansion of the external condyle with clear cut boundary and coarse trabeculation.

Figure 18, a roentgenogram taken May 6, 1934, shows the cystic area much increased in size.

Fig. 16. a, Giant cell tumor lower end of ulna, in a female aged 25. Treated by resection. b, Specimen after excision.

Fig. 7. Case 4. Giant cell tumor lower end of femur in a male aged 56. Trabeculated cystic expansion of the external condyle with a fairly thick shell.

attenuation and partial disappearance of the bony shell, a line of fracture through the upper part of the cyst.

On June 10, 1934, a midhigh amputation was performed.

Description of specimen. (1) A cystic expansion of the external condyle, with an absence of bony shell on the superficial aspect. Contents of cyst, tissue of varied consistency and color. Small amount of fluid present. (2) The knee joint showed erosion of the articular cartilage on the adjacent surfaces of the external condyle and tibial tuberosity with a strong adhesion binding the two surfaces together. *Joint almost completely fixed.*

Histological examination of the contents of the cyst revealed a typical benign giant cell tumor with no suggestion of malignancy: spindle and round cells with marked number of giant cells, particularly in relation to large areas of hemorrhage.

Here is a giant cell tumor occurring in a man of 56 years (an unusually late age) which increased in size in spite of irradiation. When first discovered the tumor could undoubtedly have been cured by curettage with the pres-

Fig. 18. Case 4. The same cyst fourteen months later, after irradiation showing considerable increase in size and attenuation of the bony shell.

ervation of a useful knee joint. Fifteen months later when a surgical opinion was sought the advanced destruction and the degenerative changes in the knee joint made amputation inevitable.

I believe it is not unreasonable to regard the case for primary irradiation as still *sub judice*. My own experience leaves me at the present time an advocate of early operative intervention. On this important aspect of the giant cell tumor problem however my mind is still open and to let.

Discussion

FREDERIC J. COTTON, M.D., F.A.C.S., Boston. Somehow the age discrimination seems less clean cut in our experience than in Mr. Platt's. We have seen a good many typical giant cell tumors in children, a good many cysts in adults, which by no means are always to be connected with lime abnormalities or parathyroid activity. One recognizes, of course, the odd solitary cysts encountered in adolescence. These are obviously dystrophic, but their origin is not clear. A parathyroid background has not been established in my cases, though to be sure many of them antedate modern exact chemistry.

The giant cell tumor is, however, a distinct entity and, as Mr. Platt has said, of varying type as to growth rate (therefore as to bone expansion) and as to tendency to recur.

The arch type is the tumor para-epiphyseal, later in a bone end, it may show some bone expansion, characterized by irregular outline, particularly by apparent trabeculation, and by a tendency to involve, progressively, all parts of a given bone. Invasion of the soft parts or of the adjacent joints occurs late if at all.

There is definite evidence to support the statement that giant cell tumors do degenerate to form cysts and transitional forms are not rarely met with.

Some confusion may arise here because real cysts of any origin may show in the lining membrane giant cells in some number. Giant cell tumors may be associated with cysts in the same individual—both of obvious parathyroid background. On the other hand, giant cell tumors which do not become cysts or retrograde into scar fibroma, may and not seldom do recur even after excision by a technique or dinarily efficient; they may very rarely give rise to chest metastases of similar apparently non-malignant histology.

It must be remembered that these giant cells are the bone eaters and that their presence in granulation tissue—for that is the mass of the tumor—may prove only the destruction of bone. They may well

be as Asaffory has called them, only "foreign body giant-cells" though this hardly explains similar tumors, as epulis or tendon sheath growths.

There is no question but that there is a definite class of giant cell growths. They are essentially benign, and usually can be diagnosed by means of the X-ray. It is true that these tumors and certain cysts have much in common in appearance and in origin.

I agree with the speaker that operation is absolutely preferable to irradiation. I would go even further and say that irradiation usually acts to stimulate the tumor growth, the curative effect beginning only later and at the expense of unnecessary deformity from loss of bone.

Only when such tumors are found in the spine (recognizable in part by the characteristic invasion of the transverse and other processes) is the X-ray to be chosen as a means of treatment. Elsewhere thorough curettage and vaseline packing to allow healing from the bottom gives permanent cure in most cases.

We have seen several cases in which patients have remained cured, at least for years, after a second operation.

We have seen one case recur after 2 years' apparent healing, reoperated upon, and become apparently well after a year; recurrences are usually rather prompt.

If a third operation is necessary, it should be resection.

We have data on but one amputation; amputation should have been done in one other case with repeated recurrence and final death from thoracic metastasis.

I am much interested in Mr. Platt's 40-year limit. One recalls in this commonwealth very, very few cases of giant cell tumors after 40 and based on the age of the patient there seems to be no exact or even nearly exact differentiation between giant cell tumors and their near cousins, the "solitary" cysts.

ENDOCRINE MECHANISMS IN CERTAIN FUNCTIONAL GYNECOLOGICAL DISORDERS¹

EMIL NOVAK, M.D., F.A.C.S. BALTIMORE, MARYLAND

NO apology need be made for discussing functional disorders before an audience of surgeons, who in the popular mind at least, are the artisans of the medical profession. Certainly in gynecology more than in any other branch of surgery an ever increasing proportion of our patients invoke the science as well as the art of our calling. If I may very immodestly quote from a previous paper of my own "If the proper study of mankind is man the proper study of gynecology is woman in all her varied biological aspects, rather than merely as a creature possessing pelvic organs of certain shape, size and position. To achieve such breadth of viewpoint a knowledge of the more static subjects of the anatomy histology and pathology of the generative organs must be supplemented by a familiarity with the physiological and endocrinological forces which vitalize these organs."

The approach to clinical problems of the gynecologist interested in endocrinology is apt to be very different from that of the man so unfortunate as never to have interested himself in this new and fertile field. To the first such a symptom as uterine bleeding may mean a careful search for anatomical causes, and if none are found an assumption of functional or perhaps even "idiopathic" etiology. His more physiologically minded confrère how ever tries to go a step further and, knowing something of the normal physiological forces tries to determine what the nature of the functional upset may be. Again where one type of gynecologist will open the abdomen with an eye only for structural deviations, the other includes in his survey a consideration of such physiological factors as may often be deduced from careful inspection of the ovaries, coupling with this the information gained from a careful history and a really comprehensive physical examination which must often include all the interlocking ductless gland structures. Innumerable examples

might be offered in support of this general thesis, and some I shall have occasion to stress later in this paper. One need no longer fear that an interest in endocrinology will expose one to the criticism of being a ductless gland faddist, and it is no mere literary overstatement to assert that a working knowledge of endocrinology is indispensable to the gynecologist who would practice his specialty intelligently.

To argue that our knowledge of gynecological endocrinology is very incomplete and that the subject is a bewildering one to the neophyte or for that matter even to investigators who have worked intensively in this field is merely begging the question. A sufficient number of facts have been crystallized out to change and to freshen our viewpoints on many old problems in both reproductive physiology and clinical gynecology and this modicum of knowledge it is not difficult to acquire. The disappointments of organotherapy should be no deterrent, as seems to be the case with many. Nothing can be much more certain than that the brilliant advances of reproductive physiology will bring their therapeutic reward in the not very distant future but we need not wait for this, to develop an interest in endocrinology. Even in its present undeveloped state it can aid much in the interpretation of clinical problems, and can make our daily work as clinicians much richer in interest and zest.

THE NORMAL CYCLE

It goes without saying that a discussion of the endocrine mechanisms in gynecological disease presupposes some knowledge of the endocrine mechanism of the normal genital cycle. A still broader knowledge will come from a study of this phenomenon from a comparative standpoint. This is not the place to review the normal physiology of menstruation. I have done this in several previous publications. As a basis for our discussion of

pathological physiology, however it may be emphasized that the rôles played by the two known ovarian hormones are now rather clearly defined. One of these hormones the hormone of the graafian follicle (estrin theelin, folliculin, "the female sex hormone" or menformon) exerts two chief effects upon the endometrium, and to a less extent the uterine musculature, viz. growth and hyperæmia. This hormone is produced not only in the developing follicle but also as we now know, in the corpus luteum which supersedes the follicle after extrusion of the egg. The more characteristic hormone of the corpus luteum progesterin, is, on the other hand responsible for the secretory changes of the premenstrual or preovulatory phase of the cycle—changes which are indispensable for the implantation of the fertilized egg.

MENSTRUAL BLEEDING

With reference to the hormone mechanism of the actual bleeding of menstruation the evidence now indicates that the responsible factor is an abrupt drop in the blood level of folliculin so that in the failure of pregnancy, the built up endometrium is suddenly deprived of its sustaining force and undergoes degeneration and desquamation with probably both a rupture and an increased permeability of the blood vessels as immediate causes of the menstrual bleeding.

I have thus briefly and baldly stated this concept of the dominant rôle of estrin with drawal in menstrual bleeding, it is supported by a wealth of evidence and is accepted by almost all of the best investigators of the problem though some recent studies of Smith and Engle throw some doubt on the correctness of this view. If it is correct, a flood of light is shed on the mechanism of a number of functional disorders familiar to all gynecologists.

FUNCTIONAL UTERINE BLEEDING

Perhaps the most important of these is the very common and often very distressing functional hemorrhage so characteristically seen in women at or near the menopausal age on the one hand, or during the pubertal or early adolescent years on the other, though not infrequent at any age during the reproductive

epoch. The bleeding in these cases may be very severe or even exsanguinating even though the pelvic organs be grossly normal.

In so far as the ovarian hormones are concerned, the mechanism of this disturbance seems now to have been clearly established. The important defect appears to be a failure of ovulation, so that the follicle continues to develop beyond the normal ovulation period, and what is most important, to produce a steadily increasing amount of estrin. So long as the endometrium is being thus supplied, it continues to grow, and bleeding does not occur. Clinically we know that such patients often exhibit non bleeding phases of even many weeks, so that, with the final onset of free bleeding, there is not infrequently and not unnaturally a suspicion of early abortion.

The endometrial picture. The endometrium subjected to such persistent and excessive estrin influence undergoes a slow vegetative proliferation, assuming the appearance for which, many years ago I suggested the designation of "swiss-cheese pattern." This I believe to represent what is essentially an enormously overdeveloped basalis, for it is the latter endometrial stratum which is most receptive to the growth effect of estrin.

There are, however, all gradations of this proliferative type of endometrium. In the most extreme forms, the endometrium is grossly, enormously overgrown and polypoid, constituting the condition formerly, and erroneously, designated as "polypoid endometritis." In other cases, the endometrium shows little or no gross increase and may even be quite scant though the histological pattern may be the same. With reference to the histological appearance, similar variations are encountered from the extreme swiss-cheese pattern with its large cystic glands side by side with those of normal caliber, to those in which the endometrium resembles that of the normal interval phase, with few or no enlarged glands. The important feature, however, is that neither on histological study nor on differential staining (for glycogen) is there any evidence of secretion in the gland epithelium, for progesterin is lacking, the follicle having persisted without ovulating and with absence of the corpus luteum as a result.

Why there should be these great differences in the grade of proliferative picture encountered in cases of functional hemorrhage I do not know. The first thought would be that the intensity and duration of the estrin stimulation is the determining factor but this does not seem to be borne out by the clinical study of these cases. Whether the degree of receptivity of the endometrium is responsible or whether some as yet unknown interaction of the ovarian and anterior hypophyseal sex hormones must be invoked remains to be seen. The possible rôle of the rate of excretion from the body of the causative hormone or hormones must also be considered, though since the bleeding and the histological picture in the endometrium are local phenomena in that tissue I do not believe that the factor of excretion rate can explain these local variations.

The pathologist who expects to see a typical swiss-cheese endometrial pattern in every case of functional hemorrhage is apt to be disturbed if he finds only a proliferative picture scarcely or not at all distinguishable from that seen in the early interval phase. Instead of straining his eyes to look for an occasional dilated gland to justify him in the diagnosis of hyperplasia, he need only recall that, just as the interval pattern is that of the basalis raised to a somewhat higher power so is the swiss-cheese hyperplasia pattern only a still higher power of the interval picture. The term hyperplasia is a misnomer in not a few cases both from a gross and microscopic standpoint. A better plan would perhaps be to designate such endometria merely as proliferative estrous, or hyperestrous, the inference being that we are dealing with a purely estrin produced picture.

Some authors have reported the finding of premenstrual secretory endometrium in cases of functional bleeding. Since no hormone except that of the corpus luteum can produce these secretory changes, this finding at once removes such cases from the category under present discussion, though they may possibly still be of functional nature. To put it another way there is little doubt that other factors than hyperestrinism may at times produce excessive bleeding even with apparently

normal organs, though my experience leads me to believe that this group is a small one. That the uterine musculature may at times be at fault, with the production of a genuinely myopathic bleeding seems probable though it is difficult to prove. The same may be said as to a possible rôle of the vascular and vasomotor systems, or for that matter of the nervous system in general. We are in almost complete ignorance of these cogs in the menstrual machinery our knowledge of the latter being almost entirely limited to its endocrinology and histology.

In the occasional case in which a secretory endometrium is found in association with supposed functional hemorrhage my own reaction has been to suspect the correctness of the diagnosis and to bear in mind the possibility of some not easily discoverable structural lesion such as a submucous myoma, a uterine polyp or a low-grade chronic pelvic inflammatory disease. This is not to deny the possibility of functional hemorrhage due to other causes than the persistent unruptured follicle, especially as we know too little of the possible rôle of other endocrine glands, such as the thyroid, in this connection. Occasionally though not often functional bleeding is clearly due to hypothyroidism and readily cured by thyroid medication.

Pathological physiology. To revert again to the pathological physiology of the common type of functional bleeding I have already stressed the fact that so long as the endometrium is receiving a steady supply of estrin bleeding does not occur. How then can we explain the bleeding phases, sometimes short, more often prolonged, often periodic, not infrequently very irregular not rarely continuous? On the basis of what is now accepted as to the hormone mechanism of menstrual bleeding in the human female, or of estrous bleeding in some of the lower animals, the obvious explanation would be that the estrin blood level undergoes drops at varying intervals, and that it is this estrin withdrawal from the endometrium which is responsible for the bleeding.

What explanation however can we make as to these intermittent drops in the estrin level? For this we must turn to the reciprocal

relations existing between the ovarian and anterior hypophyseal sex hormones. While it is true that the anterior pituitary lobe is the "motor of the ovary," and that failure of anterior pituitary function means a failure of ovarian function it has been established that the ovary in turn exerts a reciprocal effect upon the anterior lobe. The work of Moore, Hisaw and his collaborators, as well as other investigators, has shown that prolonged and excessive estrin administration is followed by inhibition of the anterior lobe function and that, with the latter in abeyance, there follows an inhibition of ovarian activity.

In our cases of functional bleeding a similar mechanism seems to operate so that when the estrin level reaches a certain point there is produced an anterior pituitary inhibition and in turn an inhibition of follicular activity in the ovary with the drop in estrin which is responsible for the bleeding phase. I have compared the mechanism to that employed in our automatic heating systems in which the production of heat is automatically shut off when the temperature of the house reaches a certain level. The interlocking relationship between the two glands is thus seen to be not only qualitative, but also quantitative, and this is true of endocrine relationships in general, a fact often overlooked.

As to the local or anatomical findings in the bleeding phase with which we are not directly concerned in this paper suffice it to say that there is no such extensive desquamation as is seen during menstruation although small, localized infarct like areas of necrobiosis are commonly seen. Schroeder believes that these small areas are the source of all the bleeding an explanation which, to me has never seemed to carry conviction. It is difficult to believe that such tiny areas could give rise to the very massive hemorrhages sometimes observed especially in view of the moderate bleeding characterizing normal menstruation where practically the entire surface is lost. Some other factor, such as increased permeability of the blood vessel walls and increased diapedesis must be invoked to explain the bleeding from a surface which grossly, at least, often appears quite intact. The histological picture during the bleeding phase, in so far

as the swiss-cheese pattern is concerned, is quite similar to that seen in the non bleeding phase, there being no such histological cycle as occurs in normally menstruating women.

So far I have discussed chiefly the ovarian hormones as direct causes of this disorder. In conformity with the general subservience of the ovary to the anterior lobe, there can be no doubt that the underlying cause is to be sought in the latter. The prolactin principle is obviously the dominating one concerned as it is with follicle ripening and the production of estrin. The absence of corpora lutea in the ovary would indicate a lack or deficiency of prolactin B, the luteinizing principle of the anterior lobe, if we accept the concept of the duality of the two principles. The fact that some excellent physiologists believe that it is the luteinizing principle which is also responsible for ovulation would explain the failure of ovulation in cases of this type. On the other hand, the recent studies of Kurzrok suggest that prolactin A is the factor concerned with ovulation if the finding of prolactin A just before the ovulation time may be accepted as evidence to this effect.

Already there is a considerable body of experimental evidence to confirm the natural assumption of the underlying rôle of pituitary dysfunction as the cause of functional hemorrhage but when we try to seek even further, for an explanation of the pituitary disturbance, we meet the same stone wall which faces us when we seek for the underlying cause of menstrual rhythm and periodicity. The secret is still sealed within the pituitary, to which all evidence points as the ruler of this rather turbulent endocrine republic.

SOME ASPECTS OF STERILITY AND FERTILITY

Women who are suffering with functional bleeding associated with hyperplasia of the endometrium are characteristically sterile, for they do not ovulate. Furthermore, since there are no functioning corpora lutea in the ovaries, there is a lack of the progesterone so indispensable for the prenatatorial changes without which implantation can not occur. And yet in many of the milder cases the bleeding is periodical like normal menstruation, and the amount of the flow may be only slightly above

normal. I emphasize this because it illustrates the fact that periodical bleeding not distinguishable clinically from normal bleeding may occasionally occur without ovulation. In the overwhelming majority of women, of course, the mechanism is of the well known ovulatory variety but the exceptions to this rule are, I believe, more frequent than has been believed. My observations lead me to think that, even if menstruation is normal, the non-ovulatory type of periodical bleeding is not rare in women near the two extremes of menstrual life when pathological function of bleeding is so often seen. A normal puberty presupposes a perfect conjunction of several endocrine phenomena, and this does not always occur. For example, the follicle ripening mechanism may be operative before the ovulating and luteinizing effects are unlimbered and an anovulatory type of periodical bleeding clinically quite similar to normal menstruation may occur. This is an adequate explanation of the well known fact that nubility and fertility are by no means invariably synchronous.

As the woman approaches the time of actual menopause it is quite possible for the cycle again to revert to the anovulatory type, the common estrin-progestin sequence being superseded by a purely estrin mechanism so far as the ovaries are concerned. At any age during the reproductive epoch as a matter of fact, such a mechanism may develop and this possibility must be borne in mind in seeking for the cause of otherwise unexplainable sterility.

There has been much discussion as to whether the anovulatory type of cycle, admittedly the exceptional type in women, is to be considered pathological. Differences in opinion on this point are explainable entirely by differences in the definition of menstruation. If the traditional definition of menstruation as a periodical discharge of blood from the uterine mucous membrane is accepted, certainly anovulatory bleeding of the periodical type under discussion comes within this definition. If on the other hand one adds to the definition the requirement that ovulation and corpus luteum formation must occur, it is obvious that anovulatory bleeding is always

pathological even though it clinically simulates normal menstruation perfectly.

Such a restriction of the definition reminds me of the rapid mental shift exhibited by the Turkish physician in a case quoted by Garriou in his *History of Medicine*. The patient was a Turkish upholsterer who during the delirium of typhus fever drank from a pail of pickled cabbage and recovered whereupon the Turkish doctor declared cabbage juice a specific for the disease. The next patient dying under this regimen however they modified the dogma by saying that cabbage juice is good for typhus provided the patient be an upholsterer.

My own viewpoint is that the time honored clinical concept of menstruation as a periodical uterine bleeding enunciated long before we knew anything of possible differences in its hormone mechanism, is the logical one to accept. Corroborative evidence of the two types of menstruation has been abundantly furnished by students of reproductive physiology in monkeys in which the cycle is so similar to that of women. The two types are seen not only in different monkeys but also in one and the same animal at different seasons of the year even though the menstrual flow itself shows no alteration in rhythm or amount.

OVULATION TEST

The occasional importance of the above facts in the study of our sterility cases is obvious. The question naturally arises as to whether or not we can determine whether the individual patient is ovulating. This can, I think, be unhesitatingly answered in the affirmative. The endometrium is the registering board of the two ovarian hormones, and we know the effects which each produces upon it. The ovulation test, as we designate it, consists simply in obtaining for microscopic examination a bit of uterine mucosa shortly before the expected onset of a period. If the woman has ovulated a corpus luteum has been formed in her ovary, progestin has been secreted and definite secretory changes have been produced in the endometrium as can be determined by simple microscopic examination with occasional differential staining for confirmation.

If on the other hand, a proliferative, non-secretory picture is found, we may conclude that there is no corpus luteum and that ovulation has not taken place. I could cite a number of instances in which this test has proved of much value. For example, in a recent patient, aged 39, in whom both tubes were blocked at the isthmus, and in whom I had planned performing resection of the closed portions and tubo-endometrial anastomosis, the finding of a non-secretory endometrium just before menstruation prevented an operation which would undoubtedly have been useless.

Once again I emphasize that the anovulatory cycle is the unusual one in women, and that in the vast majority of women a secretory type of endometrium is to be expected just before menstruation. But in the comparatively small group of cases of otherwise unexplainable sterility, where tubal patency tests, endocrine studies, metabolism determination, semen examination, and other studies have failed to reveal a cause, I am inclined to think that as opportunities for observation increase, a not inconsiderable proportion may be explained by failure of ovulation. This is especially to be sought for if the menstrual periods are somewhat free and perhaps slightly irregular.

I emphasize once more the importance of microscopic study of the endometrium in the study of functional menstrual disorders, for this tissue is a mirror of ovarian activity, and we can often learn more from it than we can from blood and urine hormone studies, important as the latter are in many cases. The quantitative hormonology of blood and urine moreover, is impracticable in everyday practice, while valuable information is often obtained from the far simpler histological studies of the endometrium.

To obtain tissue from the uterus an anesthetic is not by any means always necessary, although this would be fully justified by the value of the information gained. In the majority of cases, however, specimens for study can be obtained without anesthesia either by using a curette sufficiently small to pass through an undilated cervical canal, or by some form of suction. During the past year

or so, I have been using suction by means of the electric motor pump the cannula for introduction being a modification of the Rubin insufflation cannula. More recently still, we have modified this by building a very small serrated curette on the open end of the cannula.¹ By means of this suction curette and the electric pump we can almost always obtain sufficient tissue without anesthesia for microscopic examination, and in some cases, in which the endometrium is sufficiently loose and fluffy, can perform a fairly complete curetting. The powerful suction engendered by this method is apt to cause some pain but this is usually easily bearable and the procedure requires only a few moments. After all, however, any method which will yield tissue sufficient for diagnosis, without pain to the unanesthetized patient, should be satisfactory. If light anesthesia is required, as is sometimes the case, there is no reason why the customary dilatation and curettage should not be carried out.

The rich possibilities of this suction or suction curette technique for the investigation of other intra uterine conditions may be mentioned in passing. I need only suggest that it will furnish an excellent means of studying the day to day variations in such conditions as amenorrhoea, in some of which at least, a histological cycle does occur, as I have found in a few cases. How does such a cycle differ from the normal and what takes the place of the bleeding phase? Again, if a sufficient number of such procedures are carried out, it seems reasonably sure that embryologists will be made happy by the accidental finding of fertilized eggs in earlier phases whether implanted or unimplanted, than the 9 to 11 day old Miller ovum.

Finally, as regards the anovulatory type of cycle, it should be added that this is only one of the endocrine mechanisms which may be concerned in sterility, though with the others there is often some manifest suggestion of endocrinopathy. For example in the far more common form of sterility associated with adipsogenital dystrophy there are present also amenorrhoea and a rather characteristic type

¹A description of this simple apparatus will shortly appear in the *Journal of the American Medical Association*.

appearance of estrin occurs during the menopause would confirm this impression although it has been shown that the climacteric is an epoch of changing blood and urine bormonology with excess of estrin in some phases decrease in others, while in still others the chief feature is the excess of prolan A. I have been impressed with the infrequency of troublesome vasomotor symptoms in cases of functional menopausal bleeding commonly accepted to be produced by hyperestrinism. It would be foolish to generalize on the basis of such observations, but the widely prevalent use of estrogenic substances in the treatment of the menopausal symptoms is certainly given a measure of support by this circumstantial evidence

OTHER INTERESTING ENDOCRINOPATHIES

Another though rather rare type of endocrine disorder in which I have been much interested is that observed in association with certain ovarian tumors which, among other endocrine effects, produce at times a remarkable change in secondary sex character. One not very rare group of tumors, the granulosa cell carcinomata exhibit a strong hyperfeminizing influence so that in children they bring about precocious puberty and menstruation while in elderly women they may produce an apparent re-establishment of menstruation. The opposite group the arrhenoblastomata, secrete the male instead of the female hormone and thus elicit phenomena indicative of masculinization and defeminization. These tumors, however constitute a story in themselves and one inextricably bound up with the still hazy story of sex differentiation in general so that this variety of endocrinopathy must be passed by with mere mention. For a discussion of the subject, the reader may be referred to the recent paper by Novak and Long.

I would have liked to discuss such interesting clinical applications of biological knowledge as are illustrated in the treatment of the gonorrheal valvovaginitis of children by the estrogenic substances and the treatment of undescended testis by the administration of the anterior pituitary like hormones of pregnancy urine. It might have been of interest,

too to discuss the diagnostic and prognostic application of the pregnancy tests in the management of hydatidiform mole and chorioepithelioma.

Another question inviting discussion is the possible application of the law of follicular constancy as enunciated by Lipschuetz, in the explanation of the cystic degeneration of conserved portions of ovarian tissue, and perhaps the responsibility of pituitary dysfunctions of one sort or another for many cases of cystic ovarian degeneration. Certainly the histological pictures found in such cases are quite similar to those found in the ovaries of laboratory animals after injection of pituitary extracts of one form or another.

Finally it might have been of interest to include a discussion, though it must have been a speculative one about the reverse effects of pelvic anatomical lesions upon not only the ovarian but also the pituitary function. Certainly it is difficult to explain in any other way the disturbances of menstrual amount and rhythm which are so common with uterine myomata, ovarian tumors, chronic pelvic inflammatory disease and other pelvic lesions. A comprehensive survey of the functional disturbances would also have to include many cases in which definite anatomical lesions are present in the pelvis. I need cite only one instance that of ectopic pregnancy for without question the mechanism of the endometrial bleeding characterizing this condition is a hormonal one emanating primarily from the ectopic trophoblast. Many other examples might be discussed were there time for this.

EPITLOGUE

While it is difficult to condense into a short summary the rather general discussion of endocrine relationships in which I have indulged I would again emphasize the patent indispensability of a knowledge of such matters to the gynecologist who would practice his specialty intelligently. An interest in endocrinology will change one's whole clinical viewpoint, and will freshen one's interest in many clinical problems which have threatened to become hackneyed and stale.

While our knowledge of the subject is still incomplete and in many fields only nebulous,

there is perhaps no branch of medicine in which such rapid strides have been made in such a short time. Thus far investigators have been studying chiefly the broad qualitative aspects of endocrine relationships but there is reason to believe that future work will reveal that endocrine equilibrium connotes a finely balanced quantitative relationship between the various endocrine organs. Another broad principle in need of elucidation is the rôle played by the variations in sensitivity of the recipient tissues to endocrine influences and the factors governing such variations for this seems just as important as the study of the endocrine dysfunctions themselves.

Discussion

DR. GEORGE VAN S. SMITH, Brookline. Dr. Novak's lucidity in dealing with these hormone mechanisms calls forth deep admiration on my part. His conservative but free thinking has been of real aid to us all in crystallizing our present knowledge.

Dr. Novak speaks of the sustaining force that estrin has in preventing the endometrium from degenerating and desquamating. In confirmation of this, it has been observed that very large amounts of estrin given just before menstruation have resulted in a lessened or even a scanty flow. Furthermore, the more or less intact estrous endometrium of typical dysfunctional bleeding supports the idea of the sustaining ability of estrin. However our knowledge of what happens at the time of conception, and the ability of progesterin to prevent or stop bleeding in women or experimentally in monkeys, makes it necessary to consider the luteal hormone a sustaining factor also.

I hesitate to complicate by theoretical considerations the clear description that Dr. Novak has presented of the endocrine situation in endometrial bleeding but feel that a few points might be brought out to demonstrate that the picture is not yet complete.

Hæmorrhage into the follicle ruptured by ovulation is well known. Careful studies show that at the time of ovulation there is actual extravasation into the endometrial stroma and occasionally blood is passed from the uterine cavity. Could this bleeding be due to a drop in the level of estrin? It does not seem so since estrin is known to be on the increase at this time.

If endometrial flow is the result solely of the removal of the two sustaining factors, estrin and progesterin, why is it that other animals with regular ovulatory cycles do not show this phenomenon? Dr. Novak has found evidence of an ovulatory cycle in women with amenorrhoea by histological studies of the endometrium and we have demonstrated the same thing by the finding of cyclic rises and drops

Many other fields of investigation, rich in promise to both scientist and clinician, lie before us. The laboratory investigator must bear the brunt of the burden but the clinician can be if he will a valuable co-worker rather than a mere parasite. This is possible only if he has prepared his mind by familiarizing himself as fully as possible with what has already been accomplished. His insight into his clinical problems will be clearer and deeper if he views them with one anatomical and one physiological eye, harmoniously co-ordinated so as to bring these problems into sharper focus than it is possible to do in another way.

in the excretion of estrin in a woman with complete amenorrhoea of 3 years duration. That actual ovulation occurs is proved by the fact that these patients do become pregnant. Why do they not bleed? Conversely why do both women and monkeys at times menstruate (I use the term guardedly) without previous ovulation or corpus luteum formation and when they do so would one not expect the flow to be excessive and prolonged? Furthermore as Dr. Novak points out, excessive bleeding may occur in patients whose endometria do not show marked estrin changes. My object in raising these points is to stress Dr. Novak's feeling which we also share that a drop in the level of estrin cannot be the only precursor of bleeding and that we must seek another factor or combination of factors in order to explain these discrepancies.

In support of this idea of another factor or combination of factors as a cause of bleeding *per se* we have obtained, with the urine of a large proportion of patients with dysfunctional flowing a prolan A effect in immature rats, using amounts which would give negative results if they came from normal women. And almost consistently has this effect disappeared with the cessation of bleeding following treatment with the urinary prolan of pregnant women. These findings, together with the estrin drop can be considered advancing steps in the gradual elucidation of the bleeding mechanism.

At present we decidedly agree that microscopic study of the endometrium gives much more reliable information than quantitative hormone analyses do. A critical experimental study of the existing methods for extraction and biological assay of prolan and estrin in the blood and urine of non-pregnant subjects has convinced us of their inadequacy. We do not feel that we can determine even approximately the amount of prolan A excreted by a patient. Until recently we thought we had been estimating urinary estrin with a fair degree of accuracy, but now we find that the simple expedient of boiling urine with

concentrated hydrochloric acid gives values up to 10 times higher. We are thus hopefully struggling for refinements in quantitative methods and anticipate discovering in this manner much more than it is possible for examination of the endometrium alone to reveal.

I am much intrigued by the finding of a cyclical increase in weight in relation to menstruation. Weight increases have been observed in cases of migraine before attacks, at which time urinary prolan A has made its appearance. In view of the recently discovered hormonal changes in certain toxemias of pregnancy I am of the opinion that the edema seen in these conditions often has a hormonal background.

Allow me to emphasize Dr. Novak's exhortation that even in its undeveloped and apparently complex state present-day knowledge of these mechanisms is not difficult to acquire and can add much to the interpretation of clinical problems.

Dr. JUK VINCENT MERRIS, Boston. We have been privileged to hear Dr. Novak present a most interesting, entertaining, and thorough paper on a very difficult subject. It is probable that many have understood all he has related but it is more probable that some have not. The latter is not due to Dr. Novak's lack of clearness but is due to a lack of understanding of the terms used and the complexity of the problems. Most of us who are working in this field and have a satisfactory knowledge of the terminology must stop and think over his reasons for believing as he does. If certain phenomena that we have all noted in our work could be explained by some of his theories, then we should have a more intelligent conception of his subject. For example he has spoken of endometrial biopsy, and we have noted in our work in the Ovarian Dysfunction Clinic of the Massachusetts General Hospital that this slight operation upon amenorrheic patients is sometimes followed by a menstrual period. If this is true we may assume that ovulation has taken place (an observation first brought to our attention by Burch) and it should follow then that some of the pregnancies noted after the Rubin test and after lipiodol injection of the uterus and tubes can be explained. For if ovulation takes place in certain instances after instrumentation of the uterine cavity conception might perhaps occur. It has long been noted that after a dilatation and curettage of dysmenorrheic and amenorrheic patients the patients' periods become more regular and less painful, and that fertility is raised. Perhaps instrumentation of the uterine

cavity by restoring ovulation and normal menstruation, is responsible for some of our successes.

Again it has been noted by all of us that after a thorough curettage of the patient with abnormal uterine bleeding a normal menstrual rhythm frequently follows. This may be due not so much to the curettage and removal of the hyperplastic endometrium as to some stimulation of the pituitary gland and through it of the ovary causing a normal rhythm to follow. Many practitioners often ask why it is necessary to give radium and X-ray treatment or to operate upon patients with abnormal bleeding, since curettage has cured so many. We who are surgeons and users of radium are often at a loss to explain some of the excellent results in patients treated in this simple manner. It is quite probable that the stimulation of the endometrium or uterus may restore normality to the pituitary and ovary and therefore put an end to the abnormal bleeding. The mechanism whereby ovulation occurs following instrumentation is not clear at present, but it is interesting to note that the female rabbit ovulates only at the time of coitus and that pseudopregnancy with corpus luteum formation follows in the mouse after copulation with a sterile male.

Dr. Novak has stated that one type of abnormal bleeding is due to continuous estrin production and that there is frequently a persistent follicle and absence of corpus luteum formation. There can be no doubt of the truth of the statement, for all of us have noted these findings during pelvic operations. If the persistent follicle (usually a small cyst) is removed, normal menstruation will be resumed. It has been suggested that rupture of such a cyst during bimanual examination might restore menstruation. Such a maneuver has been described and advocated in the literature and in my practice I have noticed its effect on two occasions. It would be hazardous to advocate such a procedure but it is evident from this discussion that removal or rupture of a persistent cyst containing estrin causes the normal rhythm to be resumed and therefore Dr. Novak's explanation of such bleeding cases is certainly upheld.

There are many other practical applications and many other observations that come to our minds as we master the knowledge of what has already been worked out by men interested in endocrinology. Dr. Novak is certainly one of the foremost among such investigators and his paper this evening demonstrates his great knowledge of the subject. I would like to thank him for all I have learned from his talk tonight and from the study of many of his excellent publications.

THE UNSOLVED FRACTURE¹

KELLOGG SPEED M.D., F.A.C.S. CHICAGO ILLINOIS

BEFORE this body of surgeons, bound by clinical ties the selection of a talk on fractures should cover a practical subject which might suddenly be of interest to any one of us. The unsolved fracture is chosen for discussion because it is the major peripheral fracture of our skeleton, and because for more than a century its treatment and the results have been a matter of controversy and inquiry among surgeons and because although the results obtained today show improvement, they are not at all comparable to those of other fractures. The progress in the investigation of fracture of the neck of the femur has been along many lines which can merely be mentioned here without discussion of their details. The collection of studies and statistics gradually increases in our surgical literature, reports for the most part being based on observations and research in anatomy, physiology, pathology, roentgenology and treatment, including end results. Appended to this paper is a list of recent articles.

One hundred years ago the difficulties in treatment of this fracture which was recognized as of major importance and had already invoked years of study, were discussed by Sir Astley Cooper in his work on "Dislocations and Fractures of the Joints." He said in part "In the examinations which I have made of transverse fractures of the cervix femoris entirely within the capsular ligament I have only met with one in which a bony union had taken place or which did not admit of a motion of one bone upon the other. I believe the reason that fractures of the neck of the thigh bone do not unite is that the ligamentous sheath and periosteum of the neck of the bone are torn through, that the bones are consequently drawn asunder by the muscles and that there is a want of nourishment of the head of the bone but I can readily believe if a fracture should happen without the reflected ligament being torn that as the nutrition would continue the bone might unite,

but the character of the accident would differ, the nature of the injury could scarcely be discerned and the patient's bones would unite with little attention on the part of the surgeon."

In 1834, there were claimed to exist 19 specimens of healed fracture of the neck of the femur in the various museums of the whole of Europe including the 3 of Malgaigne at the DuPuytren museum and Tilanus 3 at the Hospital of St. Peter at Amsterdam. Hamilton was inclined to doubt the authenticity of some of these specimens and believed that many of them were the results of old rachitic or other deformities. Some of these doubts were later sustained by Basset and aired in his monograph. It was further stated by Hamilton before 1880 that the number of specimens to be found in American museums was probably as great as all those in Europe and he advised that treatment "ought to be directed to the retention of the bone in place, by suitable mechanical means for a length of time sufficient to insure bony union or for so long a time as the condition of the patient will warrant." He employed a long side splint with extension of 10 pounds applied by adhesive tape to prevent eversion of the limb but failed to employ any abduction.

Anatomical study of the neck of the femur has been directed along the lines of the architecture of the lamellar construction of the head and neck in relation to the trochanteric portion of the bone in weight bearing axis to obtain a more or less diagrammatic viewpoint of how the angulated neck carried the superimposed body and yet permitted freedom of motions in the hip joint. The internal arrangement of the bone is found to conform to the requirements of these two purposes and to fit in with the general supporting trabecular scheme of the pelvis as carried up to the spine. Another most important point has been an acceptance of the idea that the blood supply of the head and neck comes from 3 sources (1) through the ligamentum teres the arteries

¹ Fracture Orations presented before the Clinical Congress of the American College of Surgeons, Boston, October 3-10, 1914.

Fig. 1. Head removed November 4, 1933, 18 months after fracture with non-union. The dark areas show bone of original density as of the time of accident, now aseptically necrotic. The lighter areas represent efforts at bone replacement and revascularization. The cartilaginous rim seems quite intact without pitting. On the neck surface is found bone absorption and wearing away of osseous structure. The finer details and macroscopic findings have been given in other articles.

of which are shown by Chandler and Kruhsch to be present in nearly all individuals (2) the periosteal vessels and (3) capsular branches of the anterior and posterior cervical arteries. We have also come to believe that there is some extension of blood vessels through the epiphyseal plane into the head from the superior nutrient artery.

Physiological investigation has been directed toward the changes in this part of the bone during adolescence and senility and their relation to bone repair after fracture. Study of sections of the femur confirming old observations demonstrate that in senility the canal

Fig. 2. A postmortem specimen removed 4 months after fracture treated in the conventional manner. Imperfect apposition of fragments was evidently obtained with slight rotation of the head, but very little evidence in the gross specimen of any mal-position. The main portion of the head seems alive with some lighter areas around the rim as of bone replacement, but no true bony union has occurred and no effort at new bone formation has started from the trochanteric fragment. The angulation of the trabecular lines at the fracture plane and the loss of density in the trochanteric portion of the bone are apparent. The specimen does not show definite bone replacement as starting from the vessels entering via the foramen which may have been occluded or of minor caliber, yet the head is not dead as mass. No weight bearing had ever been permitted so that factor of pressure is eliminated. Note the intact cartilage. Non-union to a live head.

openings in the bone enlarge in diameter especially in the neck where the cortical shell of bone is the thinnest, but contrary to previous understanding according to Radasch the

Fig. 3. Left figure, reduced fracture of neck in a large heavy woman, 73 years old, in the conventional position and plaster dressing, May 2, 1933. The head appears viable. Right figure, same hip May 17, 1933. The patient had 18 weeks in plaster then wore a walking caliper for 7

months. The head still seems viable and the union at the neck holding. She was continued on the caliper 3 additional months and now has satisfactory functional use of the joint with no further bony changes. Union to a live head.

amount of organic material in the bone slightly increases in ages from 60 to 90 years. The average adult has 39 to 40 per cent of organic material in his femur whereas in advanced age a proportion as high as 42 per cent is maintained. The cause of fragility in old bones cannot then be ascribed to their loss of organic material with resulting change in the elasticity required for resistance to stress but must lie in the change in porosity and thinning of the bony wall, which overbalances any gain of organic material. Although repair by callus after fracture will be attempted in this senile bone, the effort must represent a distortion of ordinary healing inasmuch as the regressive changes incidental to age still go on and two conflicting processes are at work.

No accepted evidence has been offered of the exact physiological nature of the changes affecting the epiphyseal area before the occurrence of separation of the epiphysis in adolescents to prove that it is directly based on local or constitutional disease. Many instances occur in fat youths but no definite relationship between thyroid, hypoparathyroid or other endocrine disturbance accounts for all cases. Some have shown pre separation changes betrayed by a luckily made X ray examination, or symptoms of slight pain or lameness have existed prior to separation. Mild trauma or muscular action can be traced in the final cause of nearly everyone

Fig. 4. Hip of a young man 8 years after traumatic epiphyseal separation at the neck of the femur replaced accurately immobilized 16 weeks, and supported with a walking caliper 10 months. He had grown 8 inches in height following the separation with $1\frac{1}{4}$ inches shortening in the injured leg; very good final painless function; range of motion in joint restricted about 50 per cent. The head has broken down with flattening and abundant new bone has formed in the neck. Union to a head undergoing late aseptic necrosis with deformity and joint changes involving the acetabular surface.

A glimpse at the reported investigations of local pathology betrays the great interest in this phase of the fracture. Most important have been the findings in the hips of patients on whom operation was performed and the relatively scant postmortem material obtainable. The amount of tear in the capsule of the joint—rarely complete,—the character of the fracture plane, and especially its reduction and the rapid loss of bone substance in unimmobilized or reduced cases has been watched

Fig. 5. a, Impacted fracture of left neck before reduction in a heavy woman 55 years old. Manipulative reduction 5 days later on February 11, 1933. She had walked on the fracture several days and had considerable pain. Head seems viable and somewhat rotated. b, Same, both hips May 18, 1933 after conventional 18 weeks in plaster. Head

appears viable and firmly united. One year later walks very well, slight pain but no change in roentgenological findings. c, Lateral view this hip June 26, 1933. There appears to be every evidence of fair position of the head and bony union to a live head. Had been walking on caliper more than a month.

Fig. 6. Heavy male, 40 years old, 6 months after an attempted fixation of neck fracture. The trochanteric portion of the bone was pushed up by weight bearing on an unrecognized fracture and lay completely posterior to the head. Operation for bone graft into the head was planned and started. Difficulties in freeing the trochanteric fragment and hemorrhage led to shock and abandonment of operation when only a side-to-side contact had been obtained. This film represents the condition 6 months after removal from plaster and after weight bearing on a walking caliper. He has no pain, a fair range of motion, and no change in position. Apparently a union by lateral contact only without proper apposition of viable head.

The principal points of interest have been in the behavior of the head of the bone after fracture, the changes developing in it or its covering cartilage resulting in interference with blood supply, aseptic necrosis, revascularization and substitution for dead bone by newly formed bone. Studies have also been made of resulting changes in cartilage of the head of the femur and the acetabulum involving slowly progressing loss or deformity of cartilage over areas of dead bone with replacement by bone from the subchondral areas, or complete collapse depending on the length of time or the amount of unwise weight bearing permitted after fracture. Observation of patients over long periods of time coupled with roentgenological investigation has advanced our ideas of prognosis and treatment and supplemented the information gained in other branches of the study. The fate of the head separated from the neck, or attached to it in proper approximation can be followed and foretold largely by its complete or partial change of density as compared to neighboring bone. This information however still leaves something to be learned about the fracture. One cannot say in the early weeks after fracture, even in an average adult or adolescent to say nothing of a senile person whether the

head in a given case will die and yet unite to the neck, or live and unite and later break down to flatten and slowly disintegrate, after hope had been advanced of a perfect restoration. It is this great uncertainty of the fate of the head and its subsequent mechanical changes which hold this fracture in the unsolved class.

From the studies of Santos, Phemister myself and others, it is known that 4 general results are to be obtained—a dead head with no union or a real union (which is rare) a live head with no union, or a non union (which is far from uncommon). In his recent report Phemister states that he has seen 49 patients at varying periods after fracture, following different methods of treatment, of whom 17 had heads which were alive, 8 with union, 9 with non-union. There were 32 cases of complete or partial necrosis of the head with union present in 4 and non union in 28.

Pleat formation and other cartilage changes incidental to disease as described by Freund are not found after fracture, but replacement of cartilage and finally pannus formation with adherence of the head fragment in the acetabulum are seen. True ankylosis of the hip joint has been found after a healing of the neck of the femur.

Roentgenological investigation has covered a study both of the patient's bone *in situ* and of the specimens removed, coupled with the summary of the pathology and histology present. The most recent X ray advance has also done much from the popular standpoint to influence treatment.

Every surgeon should know however that not only the amount of union between head and neck can be shown on the X ray film but that even more important information can be conveyed. The film must show both hip joints and the adjoining parts of the pelvis. The amount of regional atrophy about the fracture, a natural sequence of the injury and loss of activity, the changes in the head showing by retained original density or by mottling whether the head is entirely or partly dead or is undergoing bony replacement, along with changes in configuration indicating flattening or collapse or cartilage changes may all be read from one film. The future of the fracture from the standpoint of union to live or dead

Fig. 7 a, A 57 year old woman with fracture of neck of the femur in a limb the site of an old infantile paralysis. Manipulative reduction attempted 3 weeks after accident followed by the conventional period in plaster. Only fair apposition was obtained. b Same hip 8 months later. After removal from plaster had been walking in caliper

with very little weight bearing. Non-union to dead head betrayed by the relative densities of the bone fragments. c, Same patient after a Whitman reconstruction operation had been performed. A fair functional result was obtained in this patient considering the defect in the leg from a former paralysis.

head, or a hopeless outlook which might be bettered by operative procedure of fixation or reconstruction, can be thus exposed in a series of films taken at intervals after treatment is started.

Rigorous analysis of films and results obtained by reduction or operations and careful clinical examination after months of supposed perfect reduction lead to the development of roentgenological technique for lateral views of the head and neck of the bone. The surprising result was that there had been as high a percentage of functional use and slight disability as had been found in the average case because glaring deficiencies in angulation or approximation of bony surfaces were exposed. However union was found in some instances in which complete or perfect approximation had not obtained—a condition known to exist in many fractures throughout the body.

An understanding of my title lies in a review of the care of this fracture the mechanical treatment of which was put on a rational basis by Royal Whitman 45 years ago. His suggestions have only slowly been adopted by the surgical world more rapidly in Germany than in France and England. In the United States every effort has been made to teach the basic points in the last generation, but there is still woeful lack of application of the principles laid down by him. Traction on the leg, inversion followed by abduction, are not universally used, partly because of lack of interest among many men handling these fractures and partly

because these same men including many surgeons who receive patients with this fracture do not know how to apply a comfortable casting and serviceable plaster dressing with the patient in the position of reduction. There is no excuse for this lack of treatment ability since, through Hawley's ingenuity we have been given the fracture table. For that matter a proper plaster-of-Paris dressing may be applied by use of a simple padded perineal post on the edge of a table with the patient lying on an inverted bowl as was done 30 years ago.

Failing on account of some of the points mentioned in preceding paragraphs or for other unknown reasons to get union in a satisfactory percentage of instances surgeons turned to operative attempts to force the fracture to heal or to remove the head as advised by Sir Robert Jones. In 1902 Murphy began nailing on the heads of femora. Delbet perfected his screw and hip guide a few years later and there has followed a series of different operative attempts some with some without opening the hip joint all aiming at close and exact lasting approximation of head onto neck. Ivory and bone transplants into the head via the trochanters, nails, special screws the Smith Petersen flanged nail and lately nails or screws applied along guide wires inserted through the trochanteric portion of the bone under fluoroscopic guidance—devised by Sven Johansson, Jerusalem, and others—are all being tried. Hillebrand has reported

Fig. 8. a, Fracture of neck in a 35 year old woman. Seen, reduced, and put in plaster within 2 hours after accident, December 10, 1931. b, Same patient, both hips in plaster December 1931. c, Replacement, apposition, angle of neck, all seem good. d, Same hips April 1932 just out of immobilization. Apparently good union to live head. e, Same fractured hip June 6, 1932. Union good and head viable but neck seems to bend a trifle. Has never borne any unsupported weight, worn caliper constantly. f, Same

hip September 1, 1932. Evidence of bone absorption upper edge of neck. Head outline good, union persists. g, Same hip November 1, 1932. Head mottled a little as if bone replacement were going on in it. Neck a little depressed with evidence of absorption spots upper edge. h, (See opposite page.) Same patient, both hips, December 1, 1932. Has constantly worn caliper and not returned to work. Head fragment definitely depressed and denser than that of other femur. Outline slightly oval.

favorably on the Hotz-Richard method of nailing through neck of the femur into the head and on into the pelvis. For delayed union Hey-Groves advises taking the head out and bolting it on by a bone peg before reinsertion in the hip joint violating one of the sacred sources of blood supply to the head via the ligamentum teres.

Manipulative reduction with subsequent plaster-of-Paris dressing has held the most adherents and has shown in statistical review of well handled series of cases by such men as Stern, Henderson, Campbell, and others, good results in from 60 to 70 per cent of the cases. Cotton has amplified manipulative reduction

by artificial impaction to drive the fracture surfaces together with a hammer striking on the trochanteric area in the axis of the neck after approximation of fractured surfaces. In spite of these methods of treatment, the percentage of unions with retention of live heads in patients surviving taking all ages into consideration does not satisfy Darrach and Stimson, in a series of their cases found by checking with lateral roentgenograms a high percentage of inaccurate appositions which they feel may explain an unsatisfactory percentage of bony unions heretofore obtained.

Union to a live or dead head does not always follow the quite exact approximation which

Fig. 8 continued. b Same hips March 1 1933. Increasing depression of head and neck, with mottling union still present. i, Same hips September 1, 1933. Head has increasing density and is flattened. Union persists. Caliper removed as patient refuses to wear it longer. Cannot work and walks with limp but has no pain. j Same hips December 4 1933. Neck flattened down to a right angle. Considerable restriction of motion in hip joint with definite shortening of leg. k, Same hips September 17 1934, with

further progression in neck and head flattening, fragmentation of head, increased density and dead head. Union still seems present. Pain and disability continue, patient persuaded to resume caliper again. Were changes in head due solely to vascular failure or to pressure reaction? The early prognosis of the fracture this patient suffered had been good, that is, as of union to a live head, but the life history of the fracture in 3 years has proved to be just the reverse.

must be aimed at in every case, whether obtained by manipulative, artificially impacted or operative means. When the head gives warning that it is to die, becoming aseptically necrotic in part or completely, one cannot wonder at failure of union, no matter how exact is reposition. In some individuals the trauma of fracture, the loss of or even temporary interference with blood supply add weight to the destructive processes already set up in senile bone, upsetting its physiological equilibrium and leading to its necrosis with subsequent absorption when the patient survives. It would be expected that these factors would not affect the proper healing of adolescent bones which are still in bone building health with senile changes not expected. Yet some instances of this fracture in relatively young individuals lead to dead head and non union, in the adolescent, death and degeneration of the head—in appearance strikingly similar to Legg Perthes' disease—may come on months after an apparent bony healing of

epiphyseal separation. These changes have occurred when apposition of fracture surfaces has been most satisfactory, they are evidently either an expression of further progress of the unknown pathological changes present in the epiphysis before the separation, possibly leading to changes comparable to those of senility or of too early functional use of the newly healed bone.

Weight bearing or pressure which exists on the head of the bone from the very moment of reduction or continues on the active process of attempted bone healing, is the one factor which seems understandable as leading to delayed non union, aseptic necrosis of the head, and deformity of the hip with joint changes. If we concede that it is largely pressure which causes absorption of the neck after untreated fracture, a similar pressure may act untowardly after reduction with Whitman's method, by too early display of force against the capital portion of the bone as yet unable to withstand it on account of internal vascular changes. It

Fig. 9 a, Recent fracture of neck, July 19, 1938, in a 53 year old woman. This occurred during an attack of sleeping sickness exact date was concealed by attendants as she may have been allowed to fall out of bed. Head appeared viable compared to the other femur. b, Same hip, December 5, 1938. Operative reduction was performed the edges of the two fragments cut back with a chisel and surfaces fitted together in exact apposition under the eye. Eighteen weeks in plaster followed, then walking in a caliper. c, Same hip, February 5, 1939. Head appears viable and union firm. Joint space seems narrowed but function very good. d, Same hip, January 9, 1932, at least 3 1/2 years after fracture. Solid unyielding union to live head. If a bone transplant, screw or device other than simple replacement after freshening had been employed credit for final union and live head might have been given the internal splint. This case makes one doubt the necessity and possibly the value of any mechanical internal fixation.

Fig. 10 a, Neck fracture September 6, 1933, in a young woman 19 years old 7 months after injury. She had been given 6 weeks' immobilization in plaster. Non-union to a live head with much pain and disability. b, Same fracture after operation, June 20, 1934. Surfaces had been freshened and held by autogenous bone graft. After 18 weeks in plaster she was allowed to walk in a caliper. Head alive, union apparently promising. c, Same neck, August 24, 1934. Union seems sustained, no depression of neck, head viable, bony trabeculae developing across fracture plane. Still wearing caliper. Prognosis very good. d, Lateral view of the preceding figure same date, August 24, 1934. A indicates healed fracture plane and B the imbedded transplant.

Fig. 11. a, Fracture of neck 5 months old in a heavy woman of 49 years, May 12 1934. She refused offers to be put in plaster with reduction in January 1934. Non-union pain, never been out of bed. Visibility of head questionable. b, On operating table May 25 1934. Through a small anterior incision hip joint opened. Fracture site exposed and freshened. Reduction and abduction. End of a small flexible probe introduced between fracture surfaces as guide to drill for hole to carry transplant. c, Same date as preceding, still on Hawley table. Using probe as guide, the drill has been inserted below the greater trochanter and advanced across the fracture plane, striking the probe, to enter the head fragment which can be seen and felt to move

impaled on the end of the drill. d, Same date after operation, encased in plaster of Paris. Bone transplant taken from the tibial cortex (which seems very thin here, probably on account of the preceding 5 months in bed) has been thrust into the head along the drill tract. Position satisfactory. e, September 25 1934. Just out of plaster after 18 weeks. Position same as at operation, head a little mottled, union seems started at least, as there is evidence of callus at fracture plane. Was this all due to the implantation of the bone? Will the head retain vitality or will it go on to a complete replacement, and for how many months or years must weight bearing be guarded?

is also possible that too early or too great pressure, as from unguarded weight bearing in walking, interferes with the long period of time required for the return of the bony lamellae to their full maturity—a time varying with different individuals—and leads to a

reversal of the healing process and an absorption with necrosis of the bone. Some of these changes are irreplaceable either by time or method of treatment, including greatly prolonged freedom from weight bearing, but not from active motion which is no doubt beneficial

Fig. 2. Left, 2 years after fixation of recent neck fracture in an elderly woman, patient of Dr. Hugh McKenna. Union to a live head seems present. Right, 4 years later. Union has held, head has broken down and flattened. Cartilage collapsed, bone transplant still unabsorbed, but welded to rest of femur. Did transplant cause original union? Did it interfere with circulation in the head, coming from the ligamentum teres? Did the head die and fragment on account of weight bearing after several years?

Fig. 3. a, Repair of fracture of neck in a woman 53 years old, by means of the Smith Petersen nail. The fracture occurred August 21, 1931; nail was inserted August 24, 1932. From the service of Dr. Phenister at the University of Chicago Clinics. b, Same patient. This film taken when plaster was removed on October 30, 1932. Apposition, angle of neck and penetration of nail all very good. Head appears slightly denser than surrounding bone with well-rounded outline and not spotty. Prognosis

good. c, Same hip February 7, 1933. Patient had never worn a caliper but had used crutches and not borne full weight. Much pain. The head appears aseptically necrotic in upper portion, some effort at bone replacement in the lower half which is of less density. Union, however, has not been obtained. The trochanteric portion of the bone has slipped up, the neck is depressed and the nail, strange to say, shows evidence of absorption in a notch-like area near its head and a little roughening at its extremity. It maintains its long axis but one wonders whether or not the head of the femur may not have rotated on it. This is nearly 6 months after operation. d, The same hip May 1934. Further dead head and absorption of neck. Increased absorption of the nail, elevation of the trochanter non-union to a dead head. e, Nail removed from patient. Its absorption and partial disappearance affect its stability as a fixation agent to a certain extent. If the circulation in the head has been so poor that death of it resulted, was change in nail caused solely by mechanical stress, or by action of cells or chemical agents in blood serum? Lowering of blood supply after fracture in the head in living human may not be so great as we suspect.

The average percentage of union is probably higher than it was 100 years ago but in comparison to practically all others this fracture remains unsolved. Our organization might advantageously provide for a corps study of this lagging fracture. Such a study should lead to the adoption of a more or less orthodox line of care for the recent fracture consisting of gentle reduction by traction, inversion and adjustment of the trochanteric portion of the femur to fit its displacement, followed by abduction to the degree indicated in the pre-reductive roentgenogram as necessary to restore the angle of the neck and coaptation of fractured surfaces. This reduction would be maintained by immobilization in plaster of Paris. Such a method would be practiced by most surgeons. A few might prefer to treat their patients by operation very soon after fracture employing selected methods in an attempt to minimize the period of immobilization and to avoid feared complications. All methods should be subject to proper X ray control for position and progress of healing. The convalescent period must be guarded by adequate support of the fracture plane not only during the healing and re-forming of the bone of the neck but also during the first months after release from immobilization when weight bearing is begun. At the present time there is no guarantee of 100 per cent cure. The secondary changes in hip joint and femoral head still occur, caused possibly, by vascular deficiencies or other unknown factors following even in the face of most satisfactory replacement and apposition by any method in vogue with a supposedly proper period of immobilization and freedom from weight bearing. Apparently they are immediate results of the fracture or its treatment but they seem uncontrollable by present methods of care. The fracture is still unsolved.

STERILITY WITH SPECIAL REFERENCE TO SURGICAL POSSIBILITIES¹

BETHEL SOLOMONS, M.D. F.R.C.P. F.CO.G. M.R.I.A. F.A.C.S. (How) DUBLIN, IRELAND

Late Master Records Hospital, Gynaecologist, Newcross Hospital, Dublin

Ver dulces nates venere ac primum natis (Virg. *Æneid* IV)

THERE have been efforts to divorce gynecology from surgery and surgery from obstetrics, but it has always been our opinion that obstetrics and gynecology should go hand in hand and that the practitioner of these subjects should be able to cope with any of the ordinary surgical complications which may arise in his practice. In other words, let not the women of the world be dependent for their consultants in obstetrics on practitioners who are gynecologists and who only do obstetrics in private practice. A great deal of gynecology is due to bad obstetrics and the good gynecologist may make the future confinement a safe procedure whereas the ignorant gynecologist may leave the organs in such a position that dystocia is bound to occur.

What is the surgical subject most allied to obstetrics? Some might say plastic vaginal work. We believe that the link between obstetrics and gynecology lies in the attempt to cure sterility. When this subject was chosen we found we were rushing into a hornet's nest, from which we were inclined to run for we were well acquainted with the Meaker clinic in Boston, but sterility has been our close study for upward of 25 years, so we decided to adhere to our decision.

It is not intended to go through the whole gamut of the subject; it is not intended to produce a bibliography; this is being done every day. It is hoped to deal briefly with certain aspects paying especial attention to the surgical side.

Sterility is a disease; it is a disease which can bring misery into the home. The craving for a child may become a worse disease than anything else in the world. A patient of ours has remarked: "I would not mind dying if I could only have a child."

It has been suggested that "after sterility" can be prevented by care in the premarital state; surely this must be so and if girls are taught the principles of health and hygiene the future mothers of the nation will be able to fulfill their duties. The man and woman about to marry should be taught what healthy marriage is; they should be given one of the simple and scientific books on the subject not some of the suggestive trash which is being published by even reputable firms at the present time. Ignorance of the sexual functions has produced in our experience much sterility.

A word only must be mentioned about contraception. When advice is sought on this subject it is given but a warning is uttered

Fig. 1 Author's subperitoneal Gilliam operation, first stage.

Fig. 2 Author's subperitoneal Gilliam operation, second stage.

about the possibility of sterility following the misuse of contraceptives.

A marriage should not be considered sterile until after 18 months. A woman should have no gynecological treatment for sterility (unless there are very definite other symptoms) until after 18 months. We agree with those writers who have found that about 30 per cent of cases of sterility are due to the male. In the male the most common causes are ignorance, impotence, excessive coitus, misuse of contraceptives, frigidity, and absence, paucity, or abnormality of the spermatozoa. As already stated it is not proposed to delve fully into all aspects of this subject. Suffice it to say that the sterile patient must be carefully questioned about her general health and her habits as well as her gynecological history. It would be an interesting study in this land of America to find the effect of alcohol on fertility: the sages of old were wise, and it may be remembered that the mother of Samson took a vow of temperance previous to the birth of her child. Are the babies stronger with or without Prohibition?

At a not very far distant date hormone therapy will be simplified. A separate paper could be devoted to hormone therapy in relation to sterility. The subject cannot be ignored nowadays. The effect of diet and thyrotropic hormones on the obese patient with scanty menstruation is dramatic in many instances. The diet without the drugs, or the drugs without the diet may be compared to the singer without the orchestra. At variance with other writers we have had much success in cases of hypofunction with scanty

menstruation by administering luteinizing hormones manufactured by one of the well known firms twice weekly for the first two weeks of the cycle followed by folliculin in some form in the last 2 weeks. Other writers have suggested other methods of dosage, and the matter is definitely *sub judice*. It is well that each investigator should give his own experience. Some measure of success has also been achieved by administering 6 doses of folliculin and then stopping apparently the sudden stoppage precipitates menstruation and makes an attempt to imitate the physiological cycle.

Laboratory work must seek the clue and solve the mystery of many a case of sterility. Constitutional ailments are excluded, and last but not least the gynecological surgeon is called in.

An intact hymen has been seen by the writer 11 years after marriage. A simple rupture under anesthesia will often cure the sterility. Rigidity and stenosis of the vagina, apart from hysterical vaginismus are well known causes. This can nearly always be successfully treated by thorough digital widening followed by the insertion of a large vaginal dilator, this is kept in position by tapes around the waist and is shown to the patient after removal. It has not been found necessary to perform plastic operations on the vagina. Such factors as the reaction of the vagina will not be dealt with here.

The cervix In order to cure sterility, writers have gone from one extreme to the other

Fig. 3 Third step in author's subperitoneal Gilliam operation

Suggestions have been made by some that any manipulation of the cervix is futile by others that very radical measures are necessary. We have had in our own practice examples of pregnancy after the passage of the uterine sound and this is especially notable where there is a definite plug of mucus present—usually more than this is required. Dilatation of the cervix with some modification of Hegar's dilators or gradual dilatation by means of sea tangle tents is followed in numerous instances by pregnancy provided there are no other pathological conditions present.

It has long been a matter of dispute as to which of these latter methods is the better and we are so frankly agnostic that we use each procedure in 50 per cent of our cases with somewhat similar results. The great advantage in the tent method is that when the Rubin technique is used and the tubes are found to be normal no anesthetic is necessary for the introduction of the tent.

We have discontinued altogether all such operations as anterior division of the cervix, Pozzi's operation. We tried them for many years—a thorough dilatation is safer. Dilatation is continued until just before the start of tearing i.e. until it is believed that the next dilator will tear the cervix. The danger of all such operations as those mentioned is that unless performed with meticulous care a scar will be left from which leucorrhoea may ensue a condition most inimical to the spermatozoa.

Fig. 4. Blowing up the fallopian tube with air.

The only other operations on the cervix worth mentioning are trachelorrhaphy to cure old tears in one child sterility and the removal of erosion by means of cautery or amputation. A careful operation to cure erosion will stop leucorrhoea and will often cure a long standing one or two child sterility.

The body of the uterus. Backward displacement of the body of the uterus is a very real cause of sterility. Such displacements as retroversion with acute anteversion and anteversion with acute anteversion are congenital malpositions associated often with hypofunction and dysmenorrhoea. Apart from dilatation of the cervix, no surgical measures are required hormone therapy will help. The displacements which really concern us are retroversion usually associated with retroflexion with or without adhesions. The cure of these displacements often means the cure of sterility and a good prognosis may be given. To deal first, with retroflexion without adhesions, most of the women who consult us have no complaint except sterility. They are young women for whom pessary treatment is inadvisable. In fact very often the presence of the pessary acts as a bar to conception and operation is much to be preferred. Having done a Rubin test, followed by dilatation of the cervix, a subperitoneal shortening of the round ligaments is performed.

Since various operators seem to differ as to the best technique the operation is described and illustrated (Figs. 1-3). It is safe as to immediate and remote prognosis. It cannot cause intestinal obstruction or dystocia. It must be especially stressed that fine silk is used as recurrences have been encountered.

Fig. 5 Author's combined instrument for testing tubes and kymograph

after the use of catgut. The operation is done as follows

The abdomen is opened in the mesial line from the symphysis pubis upward. Adnexal abnormalities are corrected. A stitch of No 2 silk is placed about the round ligament on each side from 1 to 1½ inches (depending on the size of the uterus and the lengthening of the ligament) from the uterine cornu, this stitch is not tied, silk *must* be used, if catgut is the material, a recurrence of the displacement will occur. A clip forceps is placed on the edge of the rectal aponeurosis on a level with the top of the fundus uteri. A curved forceps is then passed under the aponeurosis between it and the muscle until it reaches the outside margin of the peritoneum. The forceps is then passed outside and behind the peritoneum and is brought inward until it reaches the stitch which has already been placed about the round ligament, it pulls this through. A Reverdin needle is then passed through the under surface of the aponeurosis at the outer margin of the rectus muscle, through the thickness of the ligament, and is threaded with one end of the ligature which is drawn through these structures, the same is done with the other end, and the stitch is tied. The same technique is carried out on the left side. The curved forceps may be passed through the internal abdominal ring, but there is no need to look specially for this point. The uterus is thus suspended in position by subperitoneal shortening of round ligaments, hence no danger of intestinal obstruction.

The silk is first steeped for 24 hours in ether and then for 24 hours in alcohol. After that it is boiled for 20 minutes and stored in 1 : 1000 mercuric perchloride.

Fig. 6 Author's ring forceps for control of ovarian vessels.

When adhesions are present, they are broken down. If the adhesions are complicated by tubo-ovarian trouble, these are dealt with. If the appendix is pathological, it is removed. The question of the removal of the appendix must be carefully considered. Appendicectomy in some unknown way has cured sterility or, rather, a woman who has been sterile has become pregnant after that operation. Whether the vestigial peritoneal band the ligament of Clado which connects the appendix and right ovary has anything to do with this is quite impossible to decide. Appendicectomy raises the morbidity following gynecological operations, after manipulation on the tubes it is better to leave the appendix alone. Therefore the technique, if appendicectomy is contemplated, is that this organ should be examined and removed before any attempt at salpingostomy is made.

Apart from displacements, fibroid tumors will cause sterility, for they may act as mechanical impediments especially if in the neighborhood of the cervix or they may cause ovarian dysfunction. The gynecologist should spare himself no trouble to enucleate myomata, for their removal often means a sure cure of sterility. We have taken away a single myoma the size of a fetal head including portion of the uterine mucosa we have removed multiple myomata and the results are very gratifying. It is very important in all cases to avoid the risk of intestinal obstruction. It is all important that postoperative adhesions should be avoided in case of sterility. Every effort must be made to have the uterine scar on the anterior surface of the uterus. If it must be on the posterior aspect, the scar should be covered with an omental graft. We do not suggest taking risks. If myomectomy appears in the opinion and from

SURGERY GYNECOLOGY AND OBSTETRICS

the experience of the operator to be too great a surgical risk, hysterectomy must be chosen but the risk of labor after myomectomy need not be considered

Ovaries Ovarian tumors large or small should be removed when the patient is sterile. The sterile woman with mid menstrual pain associated with sterility can sometimes be cured of both by biannual bursting of the graafian follicle under anæsthetic. If this does not cure we have after laparotomy shaved the surface of the ovary and closed the abdomen. This seems to allow an easier extrusion of the follicle. We have performed ovarian grafting in a few cases of hypofunction in the hope that the graft would stimulate ovulation. So far we have had no cures of sterility in this type of case

Adhesions Special attention must be drawn to this cause of sterility. When there is no abnormality discovered on bimanual and tube examination and the husband and wife are both normal it is worth while to open the abdomen. Adhesions of the tube or ovary to the broad ligament or pelvic wall are sometimes present. Apparently the normal path of the ovum into the tube is interfered with. The separation of these adhesions is followed by pregnancy in a sufficient number of cases to justify the procedure

The fallopian tubes The question as to the advisability of operating on the fallopian tubes for sterility has been a bone of contention for many years. This bone has been nearly picked dry but as we are especially interested in this particular phase, we intend to try to pick a little more meat from it.

We do not intend to expound to any great extent on the anatomy of the tube but attention must be drawn to several points

1 The wall gets thinner as it is traced outward from the isthmus to the infundibulum at the same time the lumen gets broader. This thinness makes it easier to form a cuff in the tube during a salpingostomy at the fimbriated end, but sutures are a little more apt to tear out. The larger lumen makes pregnancy more likely here after salpingostomy

2 The interstitial portion of the tube contains more connective tissue and is therefore less elastic and possibly less favorable for

pregnancy than the other portions. The fact that there are two definite layers of muscle, the longitudinal and circular makes for no difficulty in resection.

3 A very important fact in anatomy is the arrangement of the mucosa in permanent long folds which are simple in their inner portions but become more and more complicated as they reach the fimbriae until their appearance simulates glands, but true glands are absent. In the event of a single inflammatory attack, the gluing together of the tubal walls becomes a very real possibility. It may be well to recall that Curtis some years ago showed that a slight manipulation in the cervix may produce a temporary infection in the tubes.

Cyclical changes in the tubes Novak and Everett have made this subject very clear and showed that the tube is derived from muellerian epithelium and takes part in the cycle of menstrual changes. It is especially noteworthy that the postmenstrual phase is characterized by low epithelium which quite rapidly increases in height. It seems therefore a favorable time for tube testing salpingography and salpingostomy

After these introductory remarks, we must consider how to deal with the diagnosis and treatment of the tube in its relation to sterility. In 1909 when our interest was aroused in the subject of sterility if a dilatation of the cervix or a dilatation of the cervix with curette failed to cure we could only recommend laparotomy in order to diagnose closed tubes in those cases in which palpation diagnosis was impossible. The abdomen was then opened. If the tubes were blocked, salpingostomy was done if they were patent they were blown up from the abdominal ostium with a large ear syringe (Fig 4). Pregnancy often followed. Now Rubin's great work on insufflation and salpingography has prevented the necessity for laparotomy in numerous instances in which it was imperative before

It has been well said that there is nothing really new under the sun and without wishing to take the slightest credit from Rubin for his wonderful methods which have brought happiness to many a home the following quotation from the Aphorisms of Hippocrates, vol. ix, must be given

If a woman does not conceive, and you wish to know if she will conceive, cover her head with wraps and burn perfume underneath. If the smell seems to pass through the body to the mouth and the nostrils, be assured that the woman is not barren through her own physical fault.

This test seems to be the forerunner of the Rubin apparatus.

It is not intended to go into the details of the Rubin technique. We have followed his methods and got somewhat similar results especially with regard to pregnancies following both the inflation of the tubes with carbon dioxide and with ethdol. The latter has certain advantages over the other opaque substances in common use. It is thinner, seems to cause less pain, and requires less pressure to force it upward.

As we found that glass apparatus broke easily and was not really practical we had a tin box made with kymograph attached (Fig. 5). This kymograph does not give as complete information as Rubin's excellent instrument but it helps in giving confirmative information with regard to patency of the tubes or not. A very straight up curve means closure, a wavy curve means kinks, which can probably be overcome, a gradual curve nearly always means the tube will open at the second or third attempt. We have found especially that a round type of curve is often present in association with retroversion of the uterus. So far we have not been able to tell the site of occlusion except by definite salpingography.

If the tubes are apparently closed, the patient is left for from 3 to 6 months and if they are still closed laparotomy is advised. If laparotomy is to be done an X ray photograph should be first taken. We use the simplest possible technique merely a Rubin sound with an attachment at the end in which a record syringe can be inserted and 9 cubic centimeters of ethdol injected. Sometimes after an X ray photograph a Bonney sound is left in the cervix. When the abdomen has been opened if there is any difficulty in determining the site of closure the tubes are blown up with air from the vagina. Under what circumstances should salpingostomy be done? This question is best answered by the query: What are the contra indications?

1 The operation should never be undertaken in the presence of pyrexia, in other words, the infection should be chronic. Care must be taken to ensure that there has been no recent exacerbation of a chronic condition. We have had no trouble about this by adopting a routine sedimentation test in every case. The simple Linzenmeier technique is used, i.e., 1 cubic centimeter of blood is drawn into a syringe and mixed with a few drops of a 5 per cent solution of sodium citrate. If the blood settles in any time under 30 minutes the operation is not done.

2 If there is any likelihood of tuberculosis the operation should not be done. The presence of tuberculosis is difficult to determine. All efforts to obtain a history of tuberculosis usually end in failure. The patient refuses to acknowledge a tuberculous diathesis. A close inquiry into the family history may elicit the fact that the father, mother, or a brother or sister has suffered from the disease. Such signs as scars on the neck may help. Symptoms of tuberculosis of the tubes are more often absent than present, heavy menstruation is about the only notable feature. Such old tests as the Calmette and others were tried in many cases but they were found to be of little help. And even when the abdomen is opened, it is still impossible in a large number of cases, to say if the patient is tuberculous or not. The obvious cases speak for themselves, i.e., the mass adhesions, tubercles on the peritoneum, etc.

What should be done if the patient is known to be tuberculous? If there are masses of adhesions and tubercles pervading the abdominal cavity, if it is obvious that efforts to remove the tubes will cause escape of pus and leave raw surfaces difficult to peritonealize the patient should be left alone and radium or X ray applied later to the abdomen if ascites or troublesome symptoms arise. If, on the contrary, the removal of the tubes will be a simple matter the idea of curing sterility is abandoned and salpingectomy done taking care to core out the interstitial portion from the uterus. In our early work, we tried salpingostomy for tuberculosis of the tubes, but never saw pregnancy follow in a single case known to be tuberculous. The radical opera-

Fig. 10 Operation for disease at uterine end of tube and interstitial portion

Fig. 11 Operation on uterine end of tube and interstitial portion, second step

Fig. 12 Operation on uterine end of tube and interstitial portion, third step

Fig. 13 Operation on interstitial portion of tube

tion is a safe procedure and apparently prevents further spread of tuberculosis in the body. There is no need to do hysterectomy and it is not done unless it makes the operation simpler and safer. We have proved by curettage of the uterus before and after removal of the tubes that the removal of the latter means a cure of tuberculous endometritis. If we are not sure of our diagnosis as to whether the case is tuberculous or not, we

SOLOMONS STERILITY

treat it as non tuberculous and try resection. If trouble ensues later the remaining portion of the tube can be removed.

The cases suitable for salpingostomy. In spite of the paucity of successes after salpingostomy in certain portions of the tube, it is our opinion that the operation should be attempted for all women who want to try the last resource. The tragedy of sterility may be great and even if, as will be shown in results, the percentage of success is small, we must hope that improved technique will bring about improved results and if there are any successes at all the women must be given the chance, however small it may be. Then one can say—"All has been done that is possible if there is no result and you want a baby, adopt one." Alternatively, one can say, "This operation I am about to do has a very small percentage of results, will you have it done or will you adopt a baby?"

Our opinion, that an effort should be made to cure tubal sterility, is shared by many. It is scoffed at by others. Like many techniques, success apparently can be obtained by some practitioners and not by all. The careful choice of cases, the gentle handling of the tubes, meticulous attention to detail, all count. Various techniques have been tried. Splitting of the tubes and gouging out the uterus, as well as other numerous suggestions that have been made, have not been successful in our hands.

Success should be measured not only by the number of pregnancies but also by the patent tubes after salpingostomy.

In considering operations of the tube, we divide our cases into the following varieties:

A (1) Closed at abdominal end of the tube
(a) by adhesions, (b) by some disease in the tube

(2) Tube blocked in some portion of the isthmus (a) by kinks, (b) by disease of the tube

(3) Tube closed in the interstitial portion

(4) A combination of any of these.

(5) Tubes closed by hydrosalpinx

B Too long tubes.

C Too narrow, but patent tubes

As already stated, a very important point in technique is the handling of the tubes. We

have tried various light forceps but the fingers are the best and safest. Hemostats are necessary and we use our curved ring forceps (Fig 6) to control the ovarian vessels.

A *The tube closed at the abdominal end*

(a) by adhesions. This is the simplest case to treat and is attended by best results. The adhesions are separated and the ostium examined. If there is any bleeding surface, a plait of No 4 Luken's catgut is inserted in the lumen to prevent adhesions reforming. At the suggestion of Tweedy the insertion of catgut in the tube during these various operations has been done by us for the last 20 years and numerous varieties of technique have been tried. It is a routine procedure and the tubes have been demonstrated patent in certain cases where it seemed impossible that they could keep open without this measure.

(b) *Disease in the tube.* This is usually a chronic condition following gonorrhea or some postabortive or puerperal infection in the one child sterility case. It is sometimes necessary to remove a portion of the fimbriated end. The following is then done: all bleed and a plait is inserted (Fig 7). Occasionally we have made a definite cuff by rolling back a portion of the tube but a mere oversewing of the tube shows better results on testing.

Tube blocked in some portion of the isthmus. This can be felt and has been shown by salpingography. The following operation is performed (Figs 8, 9). The vessels in the tubal mesentery are tied, the diseased portion is removed without clamping the tubes, a piece of catgut is then passed on a long needle from the fimbriated end through the uterine ostium, the uterus is split, and the catgut knotted in the cavity. There is now a drain the whole way. The endometrial surfaces are approximated the uterus is closed and an end-to-end anastomosis is done on the tube.

If it is certain that the catgut will remain in the tube at the site of anastomosis, it is passed to the uterine ostium and the anastomosis completed without splitting the uterus.

Kinks alone in the isthmus can sometimes be loosened digitally or by snips of scissors. It is well in this type of case to have Bonney's sound in position to blow up the tubes while

the abdomen is open to ensure that they are really patent. Alternatively ethidol can be injected from the vagina and can be seen distending the tubes and in the case of open tubes, appearing at the abdominal ostium.

Tube closed in the interstitial portion (Fig 10) The following technique is practiced. All bleeding is controlled the tube is cut away from its insertion into the uterus. If the tube is healthy catgut is passed through it as above described. It is then determined that the uterine ostium is open—a sharp knife is used to shave off uterine muscle until the ostium is definitely exposed. The tube dilators which are really modified lachrymal duct dilators are now brought into action and the uterine ostium is dilated up to the largest size. The anterior wall of the uterus is now split in the midline (Fig 11). The catgut is passed through to the cavity and knotted (Fig 12). The endometrium is approximated by fine catgut sutures and the muscle wall closed by interrupted catgut sutures. The cut surface of the tube is now sutured to the uterine ostium. If the tube is diseased it is removed and the uterine ostium is exposed. It is dilated and a strand of catgut is inserted a new ostium formed and the ovary brought near to this new ostium (Fig 13).

Hydrosalpinx In this a special technique is practiced. The abdominal ostium is opened the fluid milked out the edges oversewed and catgut inserted in the lumen.

B Too long tubes It has been suggested that sterility may follow excessive length of the tubes. In early days, in intractable cases without obvious cause for the sterility a portion of the tube was removed but the results in no way justified the experiment.

C We have noticed what appeared to be great narrowing of the tubes although patent. This is apparently a very real cause and is a matter worthy of investigation. Hormone treatment is worth a trial.

It is not intended to give here the statistics of the many thousands of sterility cases which have come under our notice. Cure is easily obtained in many of them. The cures following ordinary common sense advice, the dramatic cures following the passage of a sound but especially the passage of carbon dioxide

or some opaque substance through the tubes, the cure of backward displacement the very usual occurrence of cure following both small and extensive myomectomies, are common to the practice of all of us. In a paper such as this, one would like to welcome a new comet on the horizon of gynecology one which would diffuse the light of knowledge in regard to the cure of sterility after salpingostomy but that comet, alas, is still in the womb of time. Our cures are few in spite of all efforts, yet they are enough we believe to justify a further trial of the methods of tubal resection.

We have sent a questionnaire to 366 patients who have had tubal resections but many have not replied and rightly and wrongly we have marked them off as failures. There were 28 pregnancies. The operations were as follows:

Eighteen resections at the fimbriated end
Four resections at the isthmus
Six resections in the interstitial portion

In addition there were two tubal pregnancies both after isthmial resection. Of the remaining 336 cases, patency was obtained after tube testing but no pregnancies resulted in 68. Of these:

56 were at the fimbriated end
4 at the isthmus
8 in the interstitial portion.

To sum up the statistics of 366 cases of tubal resection. There were 30 or 8.2 per cent which became pregnant and 98 or 18.5 per cent which either became pregnant or showed tubal patency after operation. Should we then advise our patients to submit to this major operation? Our answer is that the pros and the cons should be explained to the patient, and if she leaves the decision to the surgeon he should operate. Although the cures following tubal resection are not more numerous, I conclude with the hope in my heart that this paper may inspire others to make experiments which will bring about improved technique, followed by success in a large percentage of cases.

Dum spiro spero!

SUMMARY AND CONCLUSIONS

1. The paper is the result of the study of many thousands of cases of sterility

SOLOMONS STERILITY

2 Sterility can be prevented by instruction in puberty and in marriage.

3 Hormone therapy when properly carried out, effects cure.

4 Such operations as splitting of the cervix should be discouraged.

5 In the absence of displacements, tumors, and closed tubes, when the patient is otherwise normal, it is worth while performing laparotomy. Cure of sterility has resulted after separation of peritoneal adhesions.

6 The statistics of cures following such procedures as dilatation of the cervix, insufflation of the tubes, cure of backward displacement, myomectomy, etc., are not given in this paper. Cure in such cases is easy to obtain.

7 The treatment of tubal sterility is discussed. The technique of operation is described. The results of 366 operations are given.

Discussion

DR. LOUIS E. PHANEUF Boston The problem of sterility is such a complex one, that the surgical side of the question is but one part of it. Since Dr. Solomons has limited his remarks to the surgical possibilities as they apply to the female I shall confine my discussion to that particular phase of the subject.

When the rigid intact hymen is a cause of sterility a simple dilatation under anesthesia may be sufficient while in some instances, in the presence of severe vaginismus and dyspareunia, operation becomes necessary to enlarge the vaginal introitus. Tumors of the vulva interfering with normal coitus should naturally be excised.

Theoretically at least, stenosis of the cervix should not play an important rôle in the etiology since it seems logical to feel that if there is sufficient room for the passage of the menstrual discharge, there should be no obstruction to the ascent of the motile spermatozoa. Endocervicitis, however, as a sequence to lacerations and infections, with the resulting plug of mucus enmeshing the spermatozoa, is responsible for sterility in many instances. Like Dr. Solomons, I feel that anterior and posterior incisions of the cervix have no place in the treatment. I prefer the metal dilators to the sea tangle tents if the cervix has to be dilated. Endocervicitis, in my hands, has been treated successfully by coining the hymen electrically with the high frequency current, the Hyams electrode being used. This is an office procedure carried out under local anesthesia. Healing takes place during the course of from 4 to 6 weeks and the infected, hypertrophied endocervical mucosa becomes replaced by squamous stratified epithelium. I have seen pregnancy follow this method in a number of cases.

Retropositions of the uterus, *per se* are not a serious cause of sterility although we all have seen, in the absence of other causes, pregnancy follow their correction. In the congenital type of retroversion, where there exists a short anterior vaginal wall, pulling the cervix toward the symphysis, the anterior wall should be lengthened by operation before shortening the round ligaments. With a mobile uterus remaining in posterior position because of relaxed ligaments I have seen satisfactory results when the

uterine malposition was corrected by means of a well fitting pessary. I would not therefore discard this form of treatment entirely. As a complication of retrodisplacements, we frequently find adhesions of the tubes and ovaries to the broad ligaments even though the tubes may be patent as shown by the Rubin test and the injection of iodized oil. Dr. Solomons has emphasized the necessity of freeing these adhesions before suspending the uterus. I would call attention to cystic ovaries as a cause of sterility and would urge the puncture of these small cysts or even the resection of certain ovaries at the time of the pelvic operation. Occasionally marked lacerations of the pelvic floor may cause sterility by extensive relaxation of the vagina making it impossible for the seminal fluid to remain in contact with the cervix long enough to permit the entrance of the spermatozoa into the uterine cavity. A proper repair of the pelvic floor will obviously correct this defect.

Uterine fibroids are an important cause of sterility. Myomectomy in properly selected cases, has been followed by pregnancy in a high percentage of cases—as high as 33 per cent in some series. The operation, obviously cannot be performed with these results if the tumors have become too large and too numerous, because of the sacrifice of extensive areas of endometrium in their removal. The increased danger of hemorrhage and sepsis following the enucleation of a abundant large tumor should also be taken into account.

There is a marked difference of opinion as to the value of salpingostomy, tubal anastomosis, and the implantation of a resected tube in the uterine horn. Dr. Solomons reports 28 pregnancies in 366 women so operated, or 7.6 per cent. His results are as good or better than those obtained in most clinics. I am in full accord with him that in the presence of these figures, the decision for this type of operation should be left to the couple under consideration, but I personally advise against operation if the decision is left to me.

DR. SAMUEL R. MEAKER, Boston I remember hearing the late Dr. William P. Graves say some years ago that the most hopeful cases of sterility

are those in which the wife presents a pelvic lesion that can be corrected by surgery. The work of more recent years has considerably changed this situation. I should say today that the total benefits of surgical treatment are less than the total benefits of the constitutional treatment, endocrine and other of one or both partners. Nevertheless surgery continues to play and always will play an important part in the rebel of human infertility. We are fortunate to have had this opportunity of hearing the subject presented by a man who is recognized as an outstanding authority.

In one minor particular our practice here differs from that recommended by Dr. Solomons. We believe that there is at times distinct value in plastic operations designed to enlarge the os externum. Viscosity of the endocervical mucus, a common and important factor in sterility, is most difficult to correct unless free drainage can be established. Dilatation does not always prove adequate, since the cervical muscle quickly regains its tone, and in many such cases we do a small posterior median incision.

Our experience with salpingostomy is not extensive, for two reasons. First we have limited our operations to cases of amniotized-end occlusion, feeling that surgery has little or nothing to offer when blockades exist in other portions of the tubes. Second, we have further restricted the number of our operations by doing them only when all factors apart from the wife's tubes are either corrected or shown to be easily correctable. Under these conditions, we have performed nineteen salpingostomies, with insufflation of gas and injection of oil as routine items in the after-care. Ten of these patients have

conceived; one pregnancy was ectopic, and one woman has had two babies, so that the total result of the nineteen operations is eleven pregnancies, producing ten normal living children.

There is another type of surgical procedure to which we attach considerable importance in sterility. I refer to conservative operations on the ovaries, designed to remove mechanical impediments to ovulation, particularly retention cysts. One encounters some difference of opinion as to the value of such operations. It is not impossible for normal ovulation to occur in so-called polycystic ovaries, but the observation of a long series of cases has led us to conclude that retention cysts, by creating an abnormal intra-ovarian pressure, militate against the maturation and rupture of other follicles, and we believe that the careful removal of such structures increases appreciably the likelihood of normal oogenesis.

I am glad that Dr. Solomons opened his paper by emphasizing the importance of constitutional treatment, and by underlining the ever present responsibility of the husband. I am glad also that he has nothing to say in favor of curettage, for we should appreciate that ablation of the endometrium is scarcely calculated to increase the likelihood of conception. In my opinion the curette has seldom if ever cured sterility and has not uncommonly caused it.

The whole subject of involuntary sterility is one of major importance, not only from the medical but also from the social and economic viewpoints, since it profoundly affects not less than 10 per cent of the human race. We are greatly indebted to Dr. Solomons for his most timely presentation.

HYDROCEPHALUS AND SPINA BIFIDA¹

WILDER PENFIELD M.D. MONTREAL, CANADA
Director Montreal Neurological Institute

FROM time immemorial the arrival of a newborn babe with water on the brain or a deformed back has been greeted by the midwife and physician with a hopeless shrug. The mother was told that the fruit of her labor was spoiled beyond redemption. That attitude often persists even today although many of these unfortunates can be salvaged for a normal, useful life.

Hydrocephalus and spina bifida are occasionally associated from the beginning, and all too often hydrocephalus is produced by well meant but improper operation for the repair of spina bifida.

HYDROCEPHALUS

There are two separate fluid systems within the cranial cavity. The cerebrospinal fluid fills one system which extends from ventricles through extracerebral cisternae to the subarachnoid spaces over the surface of the cerebellum and cerebrum where the major portion of the fluid is reabsorbed into the blood stream. This, Cushing has aptly termed the third circulation. The other fluid collection is found in the subdural space where it is separated from the cerebrospinal fluid by the arachnoid membrane.

Recognition of the separateness of these two bodies of fluid is of the utmost practical importance. Subdural fluid normally very small in amount, is a clear yellow color, richer in protein than cerebrospinal fluid but containing similar amounts of crystalloids such as potassium, calcium and sodium salts. Indeed, if the normal cranium be frozen, thin yellow wafers of ice may be removed from this space which contrast grossly with the colorless ice beneath the arachnoid (3).

EXTERNAL HYDROCEPHALUS

The clinical importance of subdural fluid lies in the fact that when it is increased in amount there results an external hydrocephalus which on superficial examination, may be distinguishable from internal hydrocephalus but which differs from it in one important respect: it is easily curable (4).

External hydrocephalus may be a late result of a head injury, in which case the subdural fluid contains blood or blood pigment. In adults this is apt to form a subdural hematoma, while in infants the fluid part of the collection only may be colored yellow. Furthermore, chronic suppuration in the mastoid or one of the adnasal sinuses may react upon the adjacent dura in such a way as to cause exudation to pass from it into the subdural space. In adults this may be the oft unrecognized cause of the headaches associated with such extradural infections, while in infants the presence of subdural fluid is betrayed by a remarkable increase in head size.

The treatment of infantile subdural exudate is repeated fontanelle puncture. This will usually suffice to bring relief and in young children whose sutures are closing it will save the eyesight which tends to suffer early. Diagnosis may be made by careful superficial fontanelle puncture. If in doubt, the injection of a small amount of oxygen into the space gives a typical roentgenogram of subdural gas.

In adults many examples of "pseudotumor" and so called Quincke's serous meningitis are in reality due to subdural exudation. These patients are relieved as though by magic when a subtemporal decompressive craniotomy is carried out for the albuminous fluid seems to be pocketed in this space for long periods with little or no continuing formation.

In passing, it is worthy of note also that epilepsy sometimes develops in adults as a sequel to the formation of exudate secondary to sinus or mastoid infection. And I have found in these cases that subtemporal decompression results in cessation of the seizures.

INTERNAL HYDROCEPHALUS

This is to be defined as an increase in the amount and the pressure of cerebrospinal fluid associated with dilatation of a part or all of the ventricular system. Little is to be gained

by the usual classification of the condition into obstructive and communicating types. Obstructive hydrocephalus only means that the block is between ventricle and spinal theca. In communicating hydrocephalus the block is farther on in the fluid pathway.

In 44 cases studied completely both before and after death by Dr Arthur Elvidge and myself one or more blocks, usually adhesive were found in every case. The difference between them lay in the situation of the block and in its nature. So far as our experience goes there is no such thing as chronic hypersecretive hydrocephalus. The pathological cause does not lie in the choroid plexus.

There is now no valid ground for doubting that cerebrospinal fluid is poured out from the choroid plexuses within the cerebral ventricles. It passes through the aqueduct of Sylvius and fourth ventricle into the subarachnoid cisternæ where it moves forward beneath the brain and outward in the fissures of Sylvius to the subarachnoid spaces over the hemispheres forming the chief absorbing areas.¹

Although absorption is carried out to some extent in the subarachnoid space over the cerebellum and within the spinal canal and also no doubt within the ventricles themselves, the amount of absorption is ordinarily not great enough to accommodate the outflow from the choroid plexus (2).

Nature of block. Among infants, however, in the great majority of cases the obstruction is due to closure of the cerebrospinal fluid pathways by inflammatory exudate or to congenital failure of these pathways to open up when the fluid first begins to form.

In a group of 26 cases of infantile hydrocephalus reported by Dr Elvidge and myself the condition was evidently present at birth—and may therefore be called congenital—in 17 cases. It was apparent in 7 cases that it developed after birth. In those which were obviously postnatal, organized inflammatory exudate was usually found in the subarach-

noid space. In at least 5 cases it was apparent that an inflammatory process had begun *in utero* which observation favors the suggestion of Dandy that meningitis may occur before birth. Thus half probably more of the blocks are due to infection before or after birth.

Ventricular dilatation follows certain well defined rules. In children it begins proximally in the lateral ventricles and marches distally toward the block. If the block is in the basal cisternæ the fourth ventricle and the cisterna magna dilate only after this process has been under way for some time in the lateral ventricles, the third ventricle and the aqueduct of Sylvius (5). Eventually the whole ventricular system dilates equally.

Furthermore dilatation and local cerebral destruction are much more rapid beneath less resistant areas of the cranial vault. Thus decompressive removal of bone in either an adult or an infant is worse than futile. It results in rapid destruction of that particular area of the brain which has been decompressed with no permanent change in the intraventricular pressure.

Cerebral compression results gradually in cerebral destruction but the destruction of the brain due to ventricular enlargement has certain peculiarities. Although the volume of the brain tissue is progressively reduced it continues for some time to function normally and essential structures tend to be preserved. The white matter of the hemispheres seems to suffer most while the convoluted grey matter uncoils itself with less destruction. The white matter is made up of long nerve fibers each of which may give off numerous collateral branches. As the sheets of white matter are stretched it seems possible that the collateral branches are torn off. This would allow a continuation of essential function and would explain the large numbers of scattered compound granular corpuscles laden with fat that are found within the white matter of the progressively stretching hemisphere.

Localization of the block is necessary in any case for practical purposes but certain warnings should be sounded. The passage of an injected dye from one point to another may be of help, Dandy's neutral phenolsulphon phthalein or preferably indigocarmine being

In any normal patient ventriculography or encephalography demonstrates all the details of the pathway over and over again, and verifies the fact that the foramina of Luschka and Magendie are actual passages, not closed indentations except in the rare case (probably 1 in 100) where scar or syngonium will not pass from space to ventricle. Corpora in the subarachnoid space disappear completely in an hour or two. Indeed, it disappears so rapidly that 30 or 40 cubic centimeters of syngonium—more than the removed fluid—may be injected during encephalography without raising the normal fluid pressure. On the other hand it remains in the ventricles for days.

the most satisfactory. But dyes are on the whole very misleading, for small traces may appear on the other side of a complete functional block. Also the rate of absorption of dye from a cavity is not an infallible index of fluid absorption from that cavity since it may escape with some fluid through the needle tract to be absorbed in the superficial tissues.

The use of air, or better oxygen, makes localization of the block easy and indicates the extent of the dilatation but unless the procedure is followed shortly by effective therapy it may result in death because of the further rise in pressure which follows in the first days after ventriculography. Repeated ventricular puncture has the same eventual augmenting effect upon the pressure.

Intracranial pressure is raised initially by obstruction to the third circulation. This rise of pressure has certain important effects upon the intracranial circulation of blood. Arterial blood enters the large arteries at a pressure that we may call 1,300 millimeters of water. It leaves the cranial chamber normally in the dural sinuses at a pressure of 100 millimeters or less. The large veins on the surface of the brain carry blood which must be at a pressure slightly above that figure and a little above the pressure of the cerebrospinal fluid which is normally 150 millimeters.

In internal hydrocephalus the intracranial pressure varies between 300 and 500 millimeters of water. The pressure within the large cerebral veins must rise correspondingly or the thin walls of these vessels would be obliterated. Chronic hydrocephalus does not cause the systemic arterial pressure to rise, but the blood stream within the arterioles and venules of the choroid plexus must be under a much increased pressure in order to maintain a flow outward to the sinuses through the great vein of Galen for example. This vein would of necessity collapse unless its intramural pressure equaled that of the cerebrospinal fluid.

It seems probable that this increased arterial pressure within the choroid plexus and the enlargement of local capillaries which must accompany it within the choroid plexus, must produce an increased outpouring of cerebrospinal fluid even against the raised pressure

of that fluid medium. Thus the original interference with absorption may well result in a "vicious circle" of further increase in fluid production—until fluid formation is balanced by arrival at a pressure against which little or no fluid can pass out through the cell walls of the choroid.

That the venous pressure within the intracranial sinuses is greatly augmented in internal hydrocephalus is shown by the appearance of an increased number of dilated veins which appear typically in the scalp of a hydrocephalic infant. These scalp veins are fed by perforating communicators. The cyanotic appearance of the scalp itself in these patients bears the same testimony. On the surface of the dilating ventricle and in the cortical pia as well, vessels increase in number and come plenty until the time when the hemisphere wall is reduced to a membrane when the vessels disappear altogether.

Therapy. Certain lines of attack are self evident. First of all the cause of obstruction may be removed surgically in the case of a tumor. In adults it may be removed surgically also in certain cases of adhesive arachnitis, usually involving the leptomeninges of the posterior fossa. This adhesive condition seems to be inflammatory. In a number of my own cases there has been a history of a previous illness resembling influenza. Clinically the cases usually suggest a pre-operative diagnosis of cerebellar tumor. Separation of a few meager adhesions results in surprisingly satisfactory relief. It is unnecessary to say that appropriate medication may remove even a complete block in a syphilitic lesion.

Intelligent therapy calls for localization of the site of the block. Forty four of our cases of internal hydrocephalus, which will be reviewed by Dr. Elvidge, were as follows. In 21 cases the block was found to be in the subarachnoid space. In 14 cases the first block was in the aqueduct. In 3 the obstruction was in the third ventricle, in 1 it was of the foramina of Magendie and Luschka, and 3 cases presented extensive hydromyelia difficult to classify.

Removal of the block is obviously impossible in the average infantile hydrocephalus. The first block may not be the last. If an aqueduct is closed the subarachnoid space may be closed

also and it is probably impossible to open it. Thus explains the failure even in the hands of the most expert surgeons, of heroic attempts to carve out new pathways. A true obstruction of the foramina of Luschka and Magendie should be removed surgically but this is a very rare condition in our experience (1 case in 44). Simple dissection of the posterior fossa which is so effective in adult adhesive arachnitis does not suffice in infants.

Short-circuiting of the cerebrospinal circulation is occasionally effective this means making an opening from some ventricular space directly through into the subarachnoid spaces. Corpus callosum puncture has in a few rare instances on record resulted in cure. Subtemporal and subfrontal exposure of the basal cisternæ and incision through them into the third ventricle has been carried out by Dandy and by Naffziger. This may well prove to be the best site for short-circuiting.

Removal of choroid plexus has long been carried out by occasional optimistic surgeons, and all surgeons who continue to face the hydrocephalus problem require the support of forthright optimism. The choroid plexus is not the seat of the pathological cause and for that reason the procedure of removing it has been likened to the removal of the kidneys for stricture of the urethra. Nevertheless there are not a few cases in which some capacity for fluid absorption is preserved. The procedure in such cases seems rational. The best method is no doubt the cautery devised by Dr Tracy Putnam which has reduced the operative shock to a minimum.

Postural dehydration is a method of treatment invaluable for mild cases. Those cases of infantile hydrocephalus in which there is a close balance of absorptive capacity and fluid formation, gradually develop a greater absorptive capacity if they can be carried on over the first year and the balance is tipped in favor of absorption by this method.

The child should be kept continuously with the head above the sacrum. The head of the crib should be kept up as high as possible and the patient should be carried in a perpendicular position always. This reduces the pressure in the emerging cranial veins to a minimum, thus promoting absorption and decreasing

intracranial pressure. Further the diet should be concentrated as much as possible. Even small infants should be placed on a high percentage of solid food such as gruels with no water added. Success demands careful pediatric help and supervision. The concentrated diet usually makes the infant constipated.

For 10 years I have used this treatment for less severe cases of hydrocephalus and I have seen many (perhaps 10 or 12) permanent cures, particularly in cases associated with spina bifida. Fay has found dehydration helpful in this condition as in numerous others.

In conclusion the treatment of hydrocephalus demands separation of the cases of external fluid collection from internal hydrocephalus. In internal hydrocephalus there must be a careful analysis of the nature and site of the block. If the block is not removable by medical or surgical means 'short-circuiting' procedures provide a hope of success in those few cases in which the subarachnoid space remains open. Removal of the choroid plexus by simpler procedures may also have a future. But for milder cases, and as an added help to other methods of attack, *postural dehydration* will be found to be of great value.

Confession is good for the professional soul. I must therefore confess that after the cases of removable block are eliminated, after external hydrocephalus is eliminated and after the mild cases of internal hydrocephalus are set aside, I face the remaining hydrocephalic infants with an uncomfortable premonition of failure a premonition which I am sure is not shared by those surgeons chosen to discuss this paper. Dr. Mixer and Dr. Putnam.

SPINA BIFIDA

In regard to spina bifida, well directed therapy may be much more effective. Three years ago my associate, Dr. William Cone, and I presented a study of 33 cases of spina bifida and cranium bifidum and we described an operative procedure which adequately closes the defect and at the same time preserves the meningeocele sac, thus avoiding the danger of hydrocephalus as a sequel to operation (6).

Subsequent experience has amply justified our hopes for the procedure. In spina bifida there is a defect in the vertebral arches usually

posterior, occasionally anterior. In cranium bifidum the same is true. If the defect is covered with skin the spina bifida is called occulta. If in place of skin, a meningeal sac presents without nervous tissue in it, the spina bifida is said to be associated with meningocele. If the sac contains roots or attached spinal cord, the spina bifida is said to be associated with myelomeningocele. If no sac is formed at all and maldeveloped nervous tissue presents itself, the condition is termed rachischisis or vertebral splitting. Cases of rachischisis are not to be operated upon.

Spina bifida occulta calls for operation only when associated with advancing paralysis during the growth period. Up to the third month of intra uterine life spinal cord and spinal canal are equal in length. From then on the canal lengthens more rapidly than does the cord. As the brain cannot be displaced from its proper cavity the cord migrates upward or to be more accurate the canal grows downward away from the cord while the spinal roots elongate and the cord itself terminates at the first lumbar spine instead of the last sacral. In all forms of spina bifida the cord or roots are apt to be attached locally to the protrusion. Hence at any time during growth of the patient's body spinal symptoms may develop due to an increasing downward traction. This most often manifests itself as progressive incontinence of urine, or progressively increasing weakness in the feet. The only treatment is of course operation to free an attached cord or spinal roots.

Spina bifida with meningocele or myelomeningocele presents a sac—an evaginated diaphragm. This sac is ballooned out over the defect by cerebrospinal fluid. The sac tissue is made up of gelatinoid material which weeps spinal fluid on section. Histologically fluid spaces are seen within it. Blood sinuses and arachnoidal cell tufts are encountered, identical in structure and arrangement to the pachionian bodies and dural sinuses of the cranial cavity. Consequently the tissue of the sac resembles the absorbing tissue of the cerebral arachnoid. This sac is an absorbing mechanism for spinal fluid as we have shown by injection of intravital dyes during life. Further proof that this is the case, is the well

known fact that hydrocephalus may be produced by surgical amputation of this sac.

Dorothy Russell has recently pointed out that spina bifida with meningomyelocele is associated with an elongation of the bulb and cerebellum downward into the cervical canal so that the cervical roots run in a cephalad direction to their foramina of exit. She urges that this abnormality—the Arnold Chiari malformation—allows the spinal fluid to pass from the fourth ventricle downward into the spinal canal, but blocks its passage forward into the basilar cisternæ so that the meningocele sac replaces the cerebral subarachnoid spaces so far as absorption of fluid is concerned.

PLASTIC REPAIR

From this demonstration it follows at once that the proper surgical procedure for treatment of spina bifida should include preservation of this fluid absorbing tissue, which may take the form of a sac or of a sponge.

The protrusion is covered by a continuation of the skin which may be no thicker than a membrane, a circular incision should be made so as to preserve as much good skin as possible for closure. The skin and membrane which cap the protrusion are then peeled off by careful sharp dissection. The sac is opened evacuated of fluid, sutured again and rolled up in a little heap and covered by a protective layer of fascia. The fascia for this closure can usually be obtained by reflecting the covering of the muscles of the back toward the spinal defect, leaving the attachments of the fascial flaps at the margin of the defect.

The skin is then drawn together, great care being taken to put all strain upon a suture layer in the superficial fascia and not on the skin itself. The danger of infection and of hematoma formation in the dead space beneath the skin is an ever present one. Careful handling of tissue, closure with fine interrupted silk sutures, application of waterproof protective dressing, and immobilization of the infant in a prone position are among the procedures which contribute to successful healing.

What has been said above in regard to spina bifida applies equally to cranium bifidum. The defect is usually in the suboccipital region with maldevelopment of the cerebellum be

neath the defect, yet the children seem to grow up quite well except for an ataxic gait.

Well over half of the total cases of spina bifida and cranium bifidum are suitable subjects for operation with a mortality no greater than 10 per cent. Contra indications to operation are gross paralysis, pre-existent hydrocephalus, or the absence of sac, as in rachis chisis. An ulcerated or ruptured sac should be operated upon within 24 hours of birth, if possible. Otherwise 3 to 4 weeks of age is the time of election.

After operation the tendency to hydrocephalus which many of these infants will show must be combated by postural treatment and by energetic dehydration. This aids cerebrospinal fluid absorption as it does in any case of mild hydrocephalus, but further erect posture raises the pressure of cerebrospinal fluid at the level of the meningocele sac thus increasing the rate of absorption in that organ.

Such an article as this could hardly do justice to pathological anatomy. But practical therapeutics must be the primary interest of all surgeons worthy of the name. Many

infants with spina bifida are being allowed to die each year—infants who might have grown up to be normal men and women if the available surgeon had understood the principles involved in treatment. And nothing in surgery is so satisfying as the knowledge that one has saved a life when others had abandoned hope for the poor derelict.

Discussion

DR. WILLIAM J. MIXTER, Boston. Dr. Penfield has stated that confession is good for the soul that notwithstanding his investigations he faces many cases of hydrocephalus with a premonition of failure but thinks Dr. Putnam and I should not do so. I don't see why he says that I should have less of this feeling than he. In the earlier days of neurosurgery our results were far less favorable than at present and hydrocephalus has always been a neurosurgical bighor.

I agree that the usual classification of communicating and non communicating hydrocephalus is of little value. It is important, however for us to know the position of the most distal block. If it be in the aqueduct or the roof of the fourth ventricle a determined attempt to remove the block or form a false passage is in order. Some of our most spectacular cases are in this group but unfortunately the group is small. The use of dyes and ventriculography, as Dr. Penfield has stated, is uncertain and sometimes dangerous, yet these measures do help us somewhat, particularly the latter. What we really need is a test that will conclusively demonstrate block between the basal cisternae and the cerebral subarachnoid space or a fault in the absorptive mechanisms. If the block is in either of these locations (and it frequently is) all operative procedures directed toward removal of block from the aqueduct or fourth ventricle or attempts to form a new stoma

between the third ventricle and the interpeduncular cistern will be doomed to failure. Several years ago I attempted this procedure with the use of a cystoscope and though I could puncture the floor of the third ventricle the operation was not a success.

I feel as Dr. Penfield does that exposure of the basal cisternae and incision of the third ventricle is hazardous and unsatisfactory nevertheless, a short, circulating operation of this sort may be considered in selected cases when the time comes that we can definitely locate the position of the block.

I have felt that operative removal of the choroid plexus was too hazardous an operation to be of great value, but I have watched Dr. Putnam develop his technique with great interest and believe that it is by far the most satisfactory, particularly where some portion of the absorptive mechanism is still active.

Dr. Penfield has described postural dehydration and restriction of fluid intake. These I believe to be of great importance in the mild case and a useful adjunct to operative interference in the severe one.

In his discussion of spina bifida Dr. Penfield states that spina bifida occulta should be operated on only during the period of growth and if neurological signs are increasing. I should be a little more enthusiastic than that. Certain cases of spina bifida occulta have associated congenital neoplasms of the cauda equina which are removable and can be demonstrated only by operation, while others will show an increase in

neurological signs due to traction after the period of growth has ceased. Therefore, in the face of a definite percentage of unsuccessful operative procedures I should advise careful investigation of many of these cases with operative interference in mind.

Dr Penfield's idea of preservation of the sac in the treatment of spina bifida with meningocele or myelomeningocele is a distinct step forward in the treatment of this distressing condition and should materially reduce the incidence of postoperative hydrocephalus. I agree with Dr Penfield that if rupture of the sac is present at birth immediate operation is indicated, and from my own experience I would go farther and say that impending rupture is an indication for immediate operation. These tiny infants, during the first 3 days of life, are better subjects for surgical intervention than they are at 3 weeks. I am opposed to any surgical interference in patients in whom the local or neurological signs indicate irreparable and complete damage to the nerve roots supplying bladder, rectum, and legs, even if repair of the skin defect seems possible.

DR. TRACY J. PUTNAM, Boston. I am pleased that Dr Penfield emphasized the fact that cortical atrophy occurs relatively slowly as a result of increased pressure alone—perhaps no more rapidly than in adults with increased intracranial pressure. It is my impression also from both clinical experience and autopsies, that many of the infants who remain imbeciles following relief from hydrocephalus were those who suffered in the first place from a primary cortical aplasia.

I shall confine my discussion largely to the subject of hydrocephalus since it is in respect to this condition that we have experienced the new awakening of hope to which Dr Penfield has referred. Our experience with congenital hydrocephalus has been briefer than his, but I should judge happier. Perhaps I may best define my own experiences with endoscopic coagulation of the choroid by giving some brief statistics. The operation has been performed 38 times in 16 patients. In all of these patients the intracranial pressure has been decreased. Seven of them are alive and have shown no enlargement of the head or bulging of the fontanelle for periods of weeks to months. Of these patients 1 developed a diplegia apparently the result of its fourth operation. An eighth child is alive, and its intracranial pressure has been somewhat relieved, but further operations are not planned on account of the patient's general condition.

Turning to the other side of the ledger, there are 8 deaths to report. Autopsy has been performed in 3 of these. The reported causes of death have been infected meningocele, with microgyria, bronchopneumonia, microgyria and absence of the corpus callosum, bronchopneumonia with microgyria. Of

the 5 other cases, only 1 was from postoperative hyperthermia, indeed this was the only case in which death occurred within 48 hours after operation. Two patients died of respiratory infection, 1 of diarrhea, 2 patients died at home after discharge from the hospital.

Though laying myself open to the charge of optimism, I cannot help feeling that these statistics could easily be much improved. Up to the present, our policy has been to operate upon every case no matter how desperate in order to see how much could be accomplished and what the dangers of secondary damage might be. Some of the patients have been almost moribund at time of operation, others have been almost certainly doomed, as for example, the child with the leaking meningocele. We now know a little better what can be accomplished and our necropsies have shown that damage to brain tissue is slight. While it appears quite unjustifiable to pay too great attention to one's operative statistics in a disease which carries such a high mortality as hydrocephalus, we are now beginning to refuse the hopeless risks. Doubtless as a result, I have had only 1 death among the last 6 patients operated upon.

It seems to me not wholly appropriate to compare the choroid to the kidney. I doubt whether any series of bilateral nephrectomies would show a mortality as low as 50 per cent even if a few stray bits of tissue were left behind. Perhaps an apter analogy would be removal of the gall bladder for obstruction of the cystic duct.

I have sometimes considered in regard to certain of the cases reported here, whether I should not do encephalograms, or without them explore the posterior fossa and catheterize the aqueduct or loosen adhesions. I have never brought myself to do either feeling that ventriculostomy alone is a more conservative procedure. The situation would, of course, be different in a child in whom the possibility of tumor or arachnoiditis had to be considered.

While my own experience with spina bifida is small, I should like to comment briefly on Dr Penfield's remarks on this subject also. I think we can all agree that the best results are to be obtained in cases in which it is possible to do a closure in layers as he recommends. I personally should not feel justified in restricting myself to such cases, for while the mortality of operations on scissile sacs and on patients with paralysis is high, occasional good results are obtained as a small reward for much labor expended. Further we are less disturbed by the possibility of development of hydrocephalus than formerly.

The subject of the surgery of hydrocephalus is by no means closed, and all of us who are faced with the problem are looking forward to hearing Dr Penfield a full report of his survey of the splendid collection of pathological material in his possession.

THE DIAGNOSIS AND TREATMENT OF DIVERTICULITIS AND DIVERTICULOSIS¹

IRVIN ABELL, M.D. F.A.C.S. LOUISVILLE, KENTUCKY

DIVERTICULA are noted at all points in the intestinal tract from the pharyngo-oesophageal junction to and including the rectum. While accurate anatomical descriptions chiefly from postmortem studies were given by various authors—notably Virchow, Graser and Fischer—during the latter part of the last century the appreciation of their surgical significance came with the beginning of the present century the attention of the profession being directed to it by the papers of Beer, W. J. Mayo, Moynihan, Drummond, Minnery and others.

In the last 25 years the literature upon the subject has become quite voluminous based upon clinical and pathological studies of a sufficiently large number of cases to warrant accurate interpretation of pathology, diagnosis and treatment. The fact that in their symptomatology they offer a counterpart of other diseases common to the intestinal tract at the points at which they occur leads an added interest to their study. They occur as sacculations projecting from varying portions of the circumference of the intestinal tube—mesenteric, antemesenteric and lateral. They may range in number from one to several hundred. Hausman reports one instance in which 400 were found. They are usually single in the oesophagus, single or comparatively few in the duodenum and jejunum chiefly of the Meckel's type in the ileum and they reach their greatest profusion in the colon particularly in its left half. Diverticula have been described as congenital or true and acquired or false; the former containing all the coats of the intestinal tube the latter representing protrusions or herniations of the mucous and submucous coats through apertures in the muscularis. The term diverticulosis connotes the presence of such sacculations while diverticulitis implies the varying changes which occur as the result of irritation and inflammation. Pulsion diverticula of the pharyngo-oesophageal junction are observed usually at

the level of the lower border of the cricoid cartilage. They occur most frequently in men and commonly as one approaches or passes middle age representing a protrusion of the mucous membrane between the muscle fibers forming the posterior wall of the pharynx. The longitudinal muscle fibers diverge at this point to their insertion in the cricoid cartilage the gap created by this divergence is filled in with the transverse and oblique fibers of the inferior constrictor forming a thin muscular coat weaker than the remaining portion of the pharyngo-oesophageal tube. As a result of pressure from within, separation of the muscle fibers occurs coincident with a protrusion of the mucosal coat. Always small in the beginning they may attain almost incredible size; one in our series showed a capacity of one pint and extended into the chest as low as the third rib. The entrance to the sac is always on the posterior wall but the sac itself as it develops pursues a downward course along the oesophagus, far more frequently on the left than on the right side; exceptionally long ones reaching at times well into the thorax.

During the early stage of development the symptoms are obscure. The decomposition of retained food particles gives rise to irritation in the sac and at times in the larynx, causing cough and the expectoration of a tenacious mucus. Difficulty in swallowing is occasioned by the filling of the sac, the food being regurgitated into the mouth either because it cannot pass the distended sac or else because muscular contraction forces up the food which has lodged in it. Not infrequently the patient repeatedly empties the distended sac by pressure with the hand the process of getting down a satisfying quantity of food being a protracted one. Sooner or later the nutrition suffers and there is both loss of weight and strength, with more or less marked dehydration. With fairly large sacs which have not yet found their way into the thorax a visible swelling appears in the neck when they be-

come filled with food. In addition to the dysphagia large sacs may occasion hoarseness by pressure on the recurrent laryngeal nerve and dyspnoea by pressure on the trachea. The development of the sac is essentially a slow one. The history of increasing difficulty of swallowing over a long period of time, with the regurgitation of food showing no evidence of gastric digestion, strongly suggests the presence of diverticulum. The additional presence of a swelling in the neck following attempts at swallowing food makes the diagnosis fairly certain. Fluoroscopic examination, employing both anteroposterior and lateral views during which the patient attempts to swallow a barium acacia meal, will give full information as to the location, size, and shape of sac.

Curative treatment consists in extirpation. In patients debilitated by starvation and dehydration it is essential that adequate preparatory treatment be carried out before operation is undertaken. This consists in the administration of food and fluids by means of the Levine tube or catheter if either can be passed beyond the mouth of the sac, otherwise of glucose and fluids introduced intravenously and subcutaneously. In an extreme case in which there had been a weight loss of more than 100 pounds and in which all efforts to enter the oesophagus, including direct vision with the oesophagoscope, had failed, we resorted to gastrostomy as a means of giving nourishment over a sufficiently long period to enhance the safety of extirpation. When the sac has reached the thorax we prefer the two stage operation advocated by C. H. Mayo, by which procedure infectious mediastinitis can usually be avoided. The one stage operation is satisfactory for the smaller sacs. Various methods of dealing with the neck of the sac have been suggested. We have endeavored to close them with suture placing a wick of rubber tissue down to the site of closure to take care of leakage should it occur. Postoperative feeding for the first 4 days is given through a tube introduced through the nose or mouth to a point below the site of operation, after which time fluids and semi liquid foods are given until the wound heals. Deep-seated diverticula of the oesophagus are much rarer than those at the upper end, are usually of the

traction type, and rarely occasion symptoms unless associated with cardiospasm. In the latter event dilatation of the cardia will usually bring about relief of symptoms.

Diverticulosis of the small intestine, first described by Chomel in 1710, has, with the exception of Meckel's diverticulum, received no surgical consideration until within the present century, most of the records having appeared in the past decade. Diverticula are not infrequent in the duodenum, being found in all 3 of its divisions. They are less frequently observed in the upper portion of the jejunum and with the exception of the diverticulum of Meckel are seen but rarely in the ileum. In the majority of the reported cases the opening into the sac has been situated on the mesenteric side while both lateral and antemesenteric openings have been described. Both the congenital, or true, and the acquired, or false, types are found in the small intestine and are observed at all ages, the latter being most frequent at and after middle age. The former have been found in infants at birth and are usually single, they have been found with pancreatic tissue at their apices, while their most frequent location in the duodenum is near the papilla of Vater, where the pancreatic ducts are developed from duodenal buds. The acquired ones develop and produce symptoms late in life when atrophy of the muscularis, particularly the circular coat, may be a predisposing factor, they occur most frequently on the mesenteric side of the bowel where the vessels penetrate the muscularis. They vary in depth from $\frac{1}{8}$ inch to 2 inches or more. The fluidity of the contents of the small intestine is such that solid material is rarely found within these sacs although the stomata which connect the diverticula with the intestine are smaller than the cavities of the diverticula.

Chomel in 1710, Harley in 1875, and Cole and Roberts in 1920 have reported diverticula of the duodenum containing gall stones while Terry and Mugler and C. M. Watson report instances of intestinal obstruction due to the formation of enteroliths in diverticula of the jejunum. Morrison and Feldman report a primary carcinoma in a duodenal diverticulum.

Diverticulosis of the small intestine may exist throughout life without giving rise to

symptoms, being found only at autopsy. With the retention of decomposing food leading to distention, irritation and inflammation of the sac or its surrounding structures, symptoms arise. None of these are pathognomonic and a diagnosis cannot be made on clinical evidence alone. Diverticula are not infrequently associated with ulcer, cholecystitis and pancreatitis and when so the symptoms caused by the latter will predominate or else becloud the picture. Upper abdominal discomfort varying from a slight ache to severe colicky pain is one of the commonest symptoms. The pain may be relieved by food or alkali or may recur after eating and there are frequently long periods of freedom. Sour stomach, belching and nausea are at times noted. The symptoms are so indefinite and so variable simulating those of lesions of adjacent organs that clinical deduction alone will not permit a diagnosis. The condition may however be demonstrated with a high degree of accuracy with the X ray. The information which such an examination affords gives one an important lead in evaluating the significance of the presence of diverticula. Those which are discovered accidentally during routine X ray examination of the gastro-intestinal tract and which are not causing symptoms require no treatment. Those in which inflammatory changes are present may require excision. The observation of retention of barium in a diverticulum for a much longer time than is required for the emptying of the stomach associated with tenderness on point pressure, when other upper abdominal lesions are ruled out may be considered as indicating diverticulitis. In the event of associated ulcer, cholecystitis, or pancreatitis, it becomes a matter of judgment to appraise correctly the rôle played by each and to determine for or against excision of the diverticulum in addition to selecting the appropriate treatment of the associated lesion. In case of doubt or in debilitated patients in whom the excision would materially enhance the operative risk, the latter procedure may be omitted until such time as the indication for it becomes more apparent.

For patients in whom the employment of surgery is contra-indicated and for those in whom symptoms are not sufficiently definite

to warrant operation a medical treatment based on that for duodenal ulcer is most likely to give good results. When the roentgenological examination has shown the presence of spasm of the pylorus or duodenum the additional employment of belladonna will be helpful. Constipation which is a frequent accompaniment, should be relieved by appropriate measures.

The complications of diverticulums of the small intestine which demand surgery for relief are diverticulitis, suppurative peridiverticulitis, perforation and intestinal obstruction. The important anatomical points to be borne in mind are the relation of the peritoneum to the sac, the relation of the sac to the vascular supply of the intestine and the relation of the sac to adjacent structures. The latter point is particularly applicable to duodenal diverticula which may be in close relation to the common duct in front of the pancreas, behind the pancreas or buried in its head. The surgical procedure employed must be suited to the pathological condition found: invagination or excision of the sac with closure of the defect in the intestinal wall, fortifying the latter where possible with an omental fat graft, drainage of abscesses with or without excision of sac, resection of intestine or pylorus, gastro-enterostomy—all find a place in dealing with the various pathological pictures presented.

The most commonly observed diverticulum of the ileum is the persistent intra abdominal portion of the vitelline duct. This type was first accurately described by Johann Friedrich Meckel and given his name in 1812. The vitelline or omphalomesenteric duct connects the yolk sac with the midgut and normally becomes obliterated in the seventh or eighth week of fetal life, the atrophy beginning at the distal end and progressing until the lumen of the ileum is reached. The artery and veins which accompany this duct normally disappear entirely with the exception of that portion which becomes the superior mesenteric artery and vein. Complete failure or obliteration will leave a tube communicating with the ileum at one end and with the umbilicus at the other from the latter of which feces are discharged. Obliteration at both ends will

leave a tube connected by a fibrous cord either to the umbilicus or the ileum or to both. Such a remnant may give rise to tumors of various types, cysts, carcinoma, sarcoma, and malignant myoma having been reported. Obliteration at the distal end leaves a tube of varying length connected with the ileum and communicating with its cavity. It may be found at any point of the small intestine below the duodenum the usual location being from 10 to 30 inches above the ileocecal opening. Its usual attachment is antemesenteric and its length varies from a small protrusion to one (reported by Moll) 33½ inches long. Its distal end may be free or be attached by a fibrous band to the umbilicus, mesentery or adjacent organ. In shape it may be spherical, conical, bulbous, or somewhat like the finger of a glove. Its walls consist of the normal coats of the ileum, possessing at times Lieberkühn's follicles, Peyer's patches, gastric mucosa, and even accessory pancreatic tissue. Its incidence as estimated from autopsy statistics varies from 1 to 2 per cent. Surgical records have shown a varying incidence, as a rule somewhat lower than that derived from postmortem studies. This interesting vestigial remnant is responsible for a number of acute abdominal conditions which carry a potentially high mortality. It is a prolific cause of intestinal obstruction as a result of its attachment to the umbilicus or to some other portion of the parietal peritoneum, mesentery or intestine resulting in constriction by band or kinking from traction. Volvulus of the diverticulum itself has been reported as well as volvulus of the loop of ileum from which it springs. Obstruction may be produced by an intussusception, the intussusceptum having for its apex the invaginated diverticulum or the point of the ileum from which it arises. Hertzler and Gibson in 1913 reported such a case together with a careful study of 41 similar instances recorded in the literature. The average age was 13 years with 49 per cent under 10 years of age. Of the 22 resections in the series 13 died and 9 recovered, a mortality of nearly 60 per cent. Further reports are available in the literature, only recently we have observed this complication in a boy of 6 years, admitted to the hospital moribund with a

palpable mass in the right lower quadrant. A diagnosis of intestinal obstruction due to intussusception was made from the history and physical findings. Autopsy showed an invaginated diverticulum with the ileum telescoped into the ascending colon.

Inflammation of Meckel's diverticulum simulates very closely that observed in the appendix, both as regards the symptoms and the sequence of pathological events dependent upon it, for it causes diverticulitis, peridiverticulitis, abscess and perforative peritonitis. The symptoms of obstruction produced by the various lesions of Meckel's diverticulum, as well as those of the inflammatory phenomena induced by it, do not in any wise differ from those arising from other causes. The history of a persistent umbilical fistula or the finding of an ileocolic intussusception in a subject beyond the age of infancy are suggestive, so also are right-sided appendiceal symptoms in the known absence of the appendix. X-ray studies have been of little value in the recognition of Meckel's diverticulum. No one symptom or combination of symptoms, aside from the presence of a congenital umbilical fistula, can lead to any high percentage of correct diagnoses.

The important lessons to be learned from the literature on Meckel's diverticulum are that its complications possess an inherently high mortality and that prompt diagnosis, at least of an abdominal emergency, with consequent early operation is important. The procedures employed must needs suit the individual case and consist in enterostomy, release of obstructive bands and intussusception, ablation of diverticulum, resection of intestine and drainage, as indicated by the pathological findings. In view of the possible dangers from a Meckel's diverticulum, it should be removed when encountered in the course of operations for other lesions. My associate and I have seen symptomless diverticula in 31 instances, 30 in the abdomen and 1 in the sac of an inguinal hernia. Twenty nine were removed, the 2 remaining possessed such wide openings and shallow depths as to render improbable the occurrence of complications. Schaeetz (25) in 1923 pointed out that islands of gastric mucosa occur in the vitelline duct and proposed the theory of

embryonal transplantation. Later he studied 30 specimens of Meckel's diverticulum by serial section. Of these only 17 or 57 per cent, were free of abdominal elements. Three or 10 per cent showed mucosa belonging to higher segments of the small gut jejunum and duodenum. Five or 16.6 per cent presented islands of gastric mucosa, one contained pancreatic tissue and one pancreatic tissue and gastric mucosa. Muelengracht in 1918, Magend and Durant in 1922, Clubal and Hallochau and Humbert in 1924 reported instances of peptic ulcer in Meckel's diverticulum showing both hemorrhage and perforation.

Aschner and Karelitz in 1930 collected and studied 33 reported cases of peptic ulcer in Meckel's diverticulum and the ileum. The most common symptom was the passage of fresh blood and clots per rectum. It was absent in but 5 of the 33 cases, and in 1 of these anemia was noted. The periods of bleeding varied from 1 of 36 hours causing death in an infant, to a man of 28 who had repeated hemorrhages since childhood. Pain of some sort was noted in 21 cases. In many its onset being coincident with perforation. Sudden perforation was noted in 11, one third of the total number. A palpable mass was observed in 3, thus with the passage of blood suggested intussusception but the stools lacked the usual admixture of mucus and the symptoms of obstruction were wanting. Gastro-intestinal X-ray studies were made in 6 cases without giving helpful information. They suggest that unexplained cases of repeated intestinal hemorrhages in which other lesions have been excluded be subjected to exploratory laparotomy. If peptic ulcer or Meckel's diverticulum be found, the operation of choice is excision of the diverticulum with enterostomy at right angles to the long axis of the intestine. Their summary is as follows: Heterotopic gastric mucosa has been shown to occur at the umbilicus as a result of anomalous developmental structures arising from the omphalomesenteric duct. Such areas of mucosa have been demonstrated to produce a secretion containing free hydrochloric acid and pepsin with irritation, erosion and ulceration of the surrounding skin. The secretion could be excited by the ingestion of food or by local mechanical stimuli. Hetero-

topic gastric mucosa has also been demonstrated in Meckel's diverticula which have retained their connection with the lumen of the ileum. Chronic ulcers causing pain, hemorrhage and perforation, and histologically identical with peptic ulcer of the stomach, duodenum and jejunum have been described in Meckel's diverticulum and the ileum in 33 cases. In 21 of these gastric mucosa was demonstrated in the diverticulum. The ulcers occurred in the intestinal type of mucosa adjoining the heterotopic gastric mucosa, being frequently located at the neck of the diverticulum which was usually completely lined by gastric mucosa.

The occurrence of diverticulosis is observed far more frequently in the colon than elsewhere in the intestinal tract. Autopsy records would indicate its frequency in 5 per cent of all subjects over 40 years of age. While the vast majority occur at and after middle life they have been reported at much earlier ages. A. P. C. Ashurst reporting a sigmoid diverticulitis in a child of 7 years and 9 months and Erdmann one in a child under 7 years of age. Only 20 in 1,819 patients at the Mayo Clinic showing diverticulosis of the colon were under 40 years of age. Diverticula of the sigmoid are by far the most common, the descending colon also being frequently involved. It is estimated that on an average 85 per cent are found in these two portions of the colon. The rectum, transverse and ascending colon share in the distribution of the remaining 15 per cent, with infrequent similar findings in the appendix. Our series shows 6 patients presenting diverticulosis of the appendix. In one of whom a diverticulitis with perforation had occurred. Stout (28) reports an incidence of 1.89 per cent, of diverticulosis of the appendix in the cases of appendicitis operated on at the Presbyterian Hospital, New York, in 1 year. The diverticula occur between the layers of the mesoappendix, projecting from the appendix like buds and are frequently multiple. In addition to the danger of diverticulitis and perforation the simple ones afford an added risk since in the process of cutting through the mesoappendix close to the appendix they may be opened with resultant contamination of the operative field. While diverticula of the

colon may be single, they are as a rule multiple, varying in number within rather wide limits. Practically all of those observed in the colon are of the false or acquired type, the sac consisting of mucosa and submucosa covered with peritoneum. Regardless of the cause—upon which there is no unanimity of opinion—once the diverticulum is formed it becomes a bottle-shaped process, with a narrow mouth and wide body, into which the faecal current enters with the eventual formation of faecaliths. There is consequent inflammatory change secondary to the obstruction and stagnation. There are no symptoms referable to simple diverticulosis. The percentage of such cases that ultimately develop diverticulitis and present subjective symptoms is conjectural, but has been estimated at from 10 to 20 per cent. The symptoms are caused by inflammatory changes in the sac and surrounding structures, notably in the mesentery, dependent upon inadequate drainage of the sac. The faecal current in the right half of the colon is largely liquid while that in the left half tends to become more and more solid, with the result that diverticula in the left half more frequently show the presence of faecaliths which obstruct drainage and predispose to the development of inflammatory changes. The symptoms of these necessarily depend upon their character and extent. With acute inflammation in a single diverticulum they closely resemble those of appendicitis—pain, nausea, and vomiting, localized tenderness and rigidity, and increased leucocyte count. If the diverticulum happens to be situated in the caecum or ascending colon differential diagnosis will be impossible until the abdomen is opened, and because of the mimicry of appendicitis such cases are almost routinely subjected to operation. When the lesion is in the left half of the colon a pre-operative diagnosis can be more readily made. Granting the presence of a diverticulitis one of several results may follow, namely resolution, perforation with resultant diffuse peritonitis, abscess, perforation into a surrounding viscus (bladder or intestine), ischio-rectal abscess, and thickening of the gut wall, mesocolic, and surrounding fat so that obstruction of varying degrees results. Opinion is divided

as to the wisest course to pursue in the presence of an acute diverticulitis. Some prefer to pursue an expectant plan of treatment until complications arise which necessitate surgical intervention, i.e., perforation or abscess while others, notably Erdman advocate immediate operation, consisting of excision of the diverticulum with closure of the opening in the intestine or simple drainage as local conditions warrant. Since diverticula are so frequently multiple, the removal of one that presents acute inflammation affords no immunity to the remaining ones against similar changes. Erdman noted a 4 per cent record of repeated invasions in a series of 52 acute cases treated by operation.

Perforation into the peritoneal cavity produces a diffuse suppurative peritonitis not distinguishable from that produced by other infectious lesions and demands similar treatment. The peridiverticulitis, almost uniformly noted makes this complication a rare one. Both in free perforations and in those resulting in localized abscess formation attempts at repair of the perforation are in order when local conditions permit. A certain proportion of these are successful while the remainder, like those treated with drainage alone result in fistulae. The latter are usually of small caliber and frequently heal spontaneously. When persistent, secondary closure or resection can be done later after subsidence of the acute reaction lessens the hazard. The subjective symptoms noted in chronic diverticulitis consist of periodical attacks of digestive disturbance with abdominal discomfort and uneasiness and at times definite pain which is usually referred to the site of the infected diverticula. Localized soreness and tenderness can usually be elicited in the region of the diverticulitis and not infrequently a mass can be felt. Roentgenological study constitutes the most important aid in diagnosis, not only locating the site of the lesion but determining as well the extent of the involvement. Many of the chronic cases prove self-limiting presenting occasional periods of more or less activity with long intervals of quiescence. Such instances require no treatment other than supervision of diet with prevention of constipation. The oral administration of

one of the petroleum preparations and the rectal use of oil or other soothing enemata will be of help. If spasticity is revealed by the X ray the addition of belladonna or stramonium to the above regimen will frequently suffice to relieve it.

The complications induced by chronic diverticulitis which demand surgical relief are fistulae and obstruction. The fistulae may communicate with the skin adjacent intestine or bladder. The diagnosis of the former is self-evident the entero-intestinal type will usually be revealed only at operation while the enterovesical variety is evidenced by vesical irritability with the passage of feces and gas per urethram. The latter are easily demonstrated by cystoscopic examination. Operative correction of such fistulae may in some cases prove relatively easy in others it entails difficult and hazardous procedures. The excision of the tract with closure of the opening in the bowel is the ideal. In our experience this can as just stated, be readily done in some instances. In others resection of the thickened distorted bowel will be required. The enterovesical fistulae, if situated high up on both the bladder and sigmoid are accessible to manipulation and correction if however the opening is located low down in both organs, the difficulty of access combined with the inflammatory infiltration make its correction both difficult and hazardous. In such cases we have elected to do a permanent colostomy with satisfying results. Obstruction may occur in acute diverticulitis as a result of infection and edema when incomplete it not infrequently subsides under the expectant plan of treatment mentioned. When complete an enterostomy proximal to the lesion not only meets the immediate indication but often permits resolution of the diverticulitis to such an extent that no further surgery is needed. Chronic obstruction is due to hyperplasia adhesions and angulation, the so called hyperplastic, stenosing type. Resection, where general conditions do not contra indicate its employment, is the treatment of choice. As with colonic resections for other lesions, experience has shown the two-stage operation to be the safer procedure. Drainage of the bowel proximal to the obstruction allows recession

of the inflammatory phenomena at the site of the diverticulitis and the upbuilding of the patient's vitality both of which enhance the safety of the second stage. The presence of blood in the stool is noted in a small percentage of patients with the obstructive type of diverticulitis. That it is not more frequently present is due to the fact that the pathological changes are so largely extramucosal, being found in the wall of the bowel the mesocolic and surrounding fat. Jones quotes Spriggs as stating that bleeding occurred 3 times in 68 cases of diverticulitis, or 5 per cent and Rankin as stating that it occurred 33 times in 227 cases, or 17 per cent. The presence of blood in the stool which can be demonstrated with the proctoscope to come from above the lower rectum has so great a diagnostic value for carcinoma of the colon as to make the differential diagnosis between carcinoma and diverticulitis at times extremely difficult when this symptom is present. The X ray may show one or more diverticula and the lesion causing the bleeding still be carcinoma. The history the duration of symptoms, the character of defect as revealed by the X ray are all of value in reaching a decision.

A study of the recent literature indicates the incidence of carcinoma developing on diverticulitis at from 17 to 8 per cent. This incidence together with the difficulty in distinguishing between carcinoma and diverticulitis in the presence of a palpable mass or defect revealed by the X ray and associated with bleeding from above the lower rectum, makes early exploration a far safer procedure in all such cases than medical regimens which involve delay.

Discussion

DR. DAVID CHEEVER, Boston. Dr. Abell, in his comprehensive paper has summarized admirably the essential facts about abnormal pouches or diverticula as they occur in the alimentary tract from the oral cavity to the anus. In many situations they are so uncommon as to be rarely encountered even by experienced surgeons, but the possibility of their presence should always be borne in mind, to explain symptoms or physical findings which are puzzling. Meckel's diverticulum, the congenital remnant of the omphalomesenteric duct, is, however, a not uncommon cause of symptoms which are included in the barbarously ungrammatical phrase "acute surgical abdomen," meaning an acute symptom group related to the abdomen and demanding surgical interference, whether or not the exact lesion can be diagnosed. It is only necessary for us surgeons to remember if the obvious cause of symptoms is not revealed by exploration, that Meckel's diverticulum must be searched for and excluded as the possible seat of trouble. Moreover as pointed out by Dr. Abell's peptic ulcer in a diverticulum lined by ectopic gastric mucosa is a well recognized cause of pain, bleeding or perforation. Once a lesion of a Meckel's diverticulum is discovered, the course for the surgeon to pursue is usually self-evident.

The multiple acquired diverticula of the colon, often largely confined to the sigmoid and descending colon are said to occur in 5 per cent of persons 40 years of age and over and since they are always potential and often actual foci of acute or chronic infection, they merit the attention of every physician, not as rarities but as frequent sources of serious conditions. From a state of complete innocuousness they range through symptoms of every grade of severity to conditions so grave that they defy the surgeon's skill. Dr. Abell has spoken of simple diverticulitis, of slow perforation with adhesions and abscess, of fistulous openings into the bladder and other loops of the intestinal canal, of free perfora-

tion with peritonitis, and finally of chronic inflammation with induration and fibrotic thickening which ultimately leads to obstruction. Such conditions as perforative peritonitis, abscess and fistula demand no special discussion of symptomatology or treatment except to emphasize the great advantage of a preliminary colostomy in the proximal transverse colon, of permanent type, to divert the entire fecal current and permit the diseased segment to be put at rest and cleansed by through and through irrigation thus favoring resolution and subsidence of the inflammatory process and permitting whatever more radical measures seem necessary to be done under favorable conditions.

Especial interest attaches to the chronic obstructive forms of the disease. They may closely simulate carcinoma, or indeed be impossible to differentiate, and their successful treatment demands at least as much judgment and operative skill. The symptoms include varying degrees of discomfort, flatulence, pain referred especially to the lower left abdomen, constipation, obstipation, and obstruction. A mild and intermittent pyrexia and moderate leucocytosis may suggest an inflammatory rather than a neoplastic origin. Inasmuch as the lesion often involves a longer segment of the bowel than carcinoma does, a mass is more likely to be palpable—often sensitive to the touch. A barium enema shows a lesion which narrows the lumen—often more extensive than carcinoma, the presence of one or usually multiple small diverticula in the neighborhood are suggestive but of course not pathognomonic, since carcinoma is as likely to affect the colon in the 5 per cent of individuals who have diverticulosis, as in an equal number of normal persons. In instances where the inflammatory lesion is not too extensive, a peculiar saw tooth or accordion-pleated serration of the barium shadow due to deep and compressed folds of the mucosa, is quite characteristic. The finger examining by rectum can

not reach the lesion unless it is felt through the bowel wall as a pelvic mass; the proctoscope, if the process be low enough, reveals more or less occlusion with edema and thickening of the wall, but no ulceration and no blood. The significance of the presence or absence of blood cannot be too strongly emphasized; bleeding is *not* a symptom of diverticulitis since the latter is not an ulcerative process, and if blood is noted as coming from a chronic obstructive lesion above the anal canal the overwhelming probability is that it is due to carcinoma. On the other hand, while it is true that microscopic or chemical traces of blood are present in all cases of carcinoma, the small scirrhous contracting lesion often shows no gross bleeding. The association of carcinoma with diverticulosis or diverticulitis is in my opinion a pure coincidence.

The successful treatment of chronic obstructing diverticulitis of the sigmoid or descending colon may tax all the resources of the surgeon. A proximal transverse loop colostomy should be made to rest completely the diseased bowel and permit lavage. If under this plan the bowel is shown by barium enema to recover its normal contour and caliber and no complications occur it may be reasonable to risk closure of the colostomy and trust that a bland diet, avoidance of constipation and colonic lavage will

prevent recrudescence of the inflammation. Such a happy event rarely occurs, however, and resection with restoration of continuity is indicated. The surgeon's personal experience and preference will determine whether this shall be done by suture or by the Mikulicz procedure; the latter is more applicable here than in carcinoma, since the tendency to slumpy resection is of less account and there can be no grafting of the disease into the wound. The frequent necessity of dealing with adhesions and complications, and the danger of spreading an already existing infection make these operations both difficult and hazardous, and both patient and surgeon may have to be satisfied with, and thankful for, a permanent colostomy. A word must be added about patients with early stages or moderate degrees of diverticulitis. A bland diet, mineral oil to keep the stools soft, and colonic lavage will cause resolution of the process and enable the patient to carry on, in the majority of cases, but both physician and patient should know that a potentially dangerous process is merely being kept under control, and that a recrudescence should have the benefit of a surgeon's opinion.

In conclusion I wish to congratulate Dr. Abell on his interesting presentation of a very important subject—a presentation which bears the authority of very wide experience.

THE REPAIR OF DEFECTS RESULTING FROM FULL THICKNESS LOSS OF SKIN FROM BURNS¹

JAMES BARRETT BROWN M.D. F.A.C.S., AND VILRAY I. BLAIR, M.D., F.A.C.S., St. Louis, Missouri
From the Department of Surgery, Washington University School of Medicine

IF a burn destroys a large area of the full thickness of the skin the result is an open wound. Unless there is early replacement of lost skin, healing will occur by contractures of adjacent tissues and by "scar" epithelium or permanent healing may never occur (Fig. 14).

The restoration of surface losses and repair of contractures in patients appear complex in many instances but from a study of the requirements of treatment in a fairly large group of patients we have outlined the essential points of care that have usually proved of benefit for these patients.

First The general care is of primary importance and includes the exercise of patience and gentleness, and interest in the patient's welfare by all who come in contact with him. The patient should be kept free from pain and from objectionable restraints, sedatives should be used carefully, and interest in surroundings should be developed especially when the patients are children (Figs. 2D, 3C). Nutrition must be kept up, and transfusions may be required frequently.

Second The local care of the open wounds has for its object the cleaning up of the areas as quickly as possible so that the lost surface may be restored with skin grafts before damaging contractures have occurred. Surgical drainage is best accomplished by the use of saline dressings or by the continual saline bath for 1 to 3 hours a day followed by dry heat or further wet dressings (Figs. 1C and 3C). Many antiseptics (common and proprietary) and gentian violet have been used, but at present we rely on Dakin's solution if anything other than saline is thought necessary.

The use of a firm pressure dressing that is kept moist by irrigation combined with elevation, may be of great advantage for lesions of the extremities, marked improvement may be noted within 48 hours (Figs. 1, 3 and 10).

Pain should be kept down to a minimum when the dressings are removed. They may

be soaked off gradually in a bath, and it is important that some protector shall have been used next to the wound to prevent the granulations from growing up through the meshes. For this, old linen, perforated cellophane like material, or very fine mesh gauze is usually satisfactory so that dressings can be removed even from children with a minimum of discomfort. When cellulitis is controlled, grease dressings (xeroform zinc oxide, or scarlet red) on fine gauze or linen can be used, these allow the patient greater freedom, but they are not used for several days immediately preceding operation. Gentle mechanical cleansing of wounds daily is important, but care should be taken not to disturb epithelization.

Surgical drainage and pressure dressings usually result in wounds with bright red, firm granulations, free from surrounding cellulitis. Bacteriological studies have shown that it is probably easier to get sterile cultures from small wounds than from very large open areas. We have repeatedly grafted wounds when from the appearance of the granulations we have thought them to be ready, and we have had successful takes with a minimum amount of cellulitis, when pre-operative cultures have shown multiple organisms. A thorough Carrel-Dakin technique is undoubtedly an advantage but it cannot replace careful evaluation of the general condition of the patient and of the gross appearance of the granulations and surrounding tissues.

Another important result from the use of the saline bath for badly burned patients is that ordinary secondary contractures will have been straightened out by the voluntary effort of the patient without the use of traction or restraints. Most patients are extremely grateful for the bath and realize their first comfort in it, and we believe that it has occasionally been a life saving measure. There may be a bad reaction to it, however, and there is frequently an elevation of temperature. If any of these

Fig. 2. A, Complete circular burns of both legs with a 90 degree flexion deformity of the knees several months after the burn. B, Legs shown after a few weeks of daily saline baths. The granulations are clean, there is no surrounding cellulitis, the flexion deformity has been completely overcome and the legs are ready for operation. C, Patient in daily saline bath. General health much improved, and he has completely overcome the flexion deformity by active movement without splints or traction of any kind.

bad effects are too severe the bath may be omitted.

When out of the bath patients can be kept comfortably warm in a covered bed with or without dressings. This allows the patient free movement and makes nursing care easier (Fig. 2D).

Third. If large areas are to be covered it is necessary to develop a method of obtaining free skin grafts of suitable thickness in large amounts, cutting them rapidly and insuring prompt healing of the area from which the grafts are taken.

The graft that we have found most applicable over open wounds is one that includes from one half to three-fourths of the thickness of the skin. For convenience we have called this a thick split skin graft to differentiate it from a full thickness graft and from an Ollier Thiersch graft that usually includes little more than the epidermis. It might be called a thick Ollier Thiersch graft (Fig. 4).

By using a sharp knife 18 centimeters long, very large grafts may be cut rapidly and the

Fig 1 D. Patient completely healed at time of discharge 3 weeks after the last of two operations. Note complete healing of donor sites of split grafts on back, buttocks, abdomen, and thigh.

larger they are the more easily they may be applied, grafts up to 18 by 5 inches may be obtained from suitable thighs. The suction retractor described in 1929 is used routinely, with it fairly large grafts may be cut even from the abdomen (Fig 5)

These grafts are applied to the area after granulations have been carefully and smoothly shaved off or after any contractures have been fully opened by dissection, or scar tissue has been excised. They are held firmly in place with horsehair sutures all around and multiple mattressing sutures over the surface. Many stab holes are made through the graft to provide for drainage. It is important to note that the removal of granulations causes a good deal of bleeding and that over large areas it must be very carefully done or even omitted if the patient cannot stand the added bleeding. It is a help in preserving blood to have an assistant hold compresses over an area as the following one is being denuded.

The donor areas require careful dressing with a fine mesh gauze impregnated with a thick ointment (xeroform, scarlet red or zinc oxide) and held firmly in place. Healing is usually complete in 10 to 15 days, and we have

on occasion cut three "crops" of grafts from the same donor area (Figs 1, 3, 9, and 10)

At present autografts are used entirely for these repairs. By using the split grafts wherever possible, the donor areas are preserved fairly well and one is usually able to find skin enough to make acceptable repairs.

Fresh homografts are used very rarely and only when it is thought that the patient cannot stand a long operative procedure and when there is no sign of spontaneous epithelization. Homografts will usually take satisfactorily, but in our experience are always absorbed within 3 weeks. However the few days respite that the patient receives while these grafts are in place may actually be a turning point in his recovery and there may be an increased spontaneous epithelization. The use of delayed homografts stored in the patient's serum and in saline is being investigated. It is possible to use successfully autografts that have been stored for several days, but this fact is not very important clinically especially when dealing with split grafts, for they can be cut rapidly and add but little time to the operation.

In some areas, mainly about the face, the split grafts are applied as "stent" grafts, either a wax or gauze or sponge form being used over the graft which is held in place with mattress sutures from side to side.

Fourth The care of the grafted area requires a simplified method of applying a pressure dressing and of keeping it moist if neces-

sary. If the wound has been originally quite dirty and refractory to treatment before operation or if there are any reasons to fear a degree of infection that might damage the graft a wet saline dressing with irrigation tubes incorporated in it is put on and pressure is obtained over the area with sea sponges bound

on firmly with heavy gauze rolls. The dressings are kept constantly moist for 4 days at which time the first dressing is changed.

If the area is quite free from contamination a sponge pressure dressing is applied with a few layers of grease gauze over the graft (Figs 6 and 7).

Fig. 6. A, Complete burn of back with wide open-bite of lower jaw resulting from traction on the jaw by scars. B, Sponge pressure dressing after first operation. C, The deformity has been released and the entire front of the neck covered with thick split grafts, shown here at time of first dressing. The sponges have made an accurate cast of the area. D, Final result with complete function and complete spontaneous correction of the open-bite. The contour and smoothness have been effected by putting in a wide full thickness graft directly across the front of the neck. The helix of the right ear has also been restored.

Fig. 7. A, Growth of arm to side from wide skin loss over arm, chest, axilla, and both axillary folds. B, Fixation of dressing after application of thick split grafts. A quilted bed pad is incorporated over the sponge pressure dressing and held with gauze rolls and adhesive. C, First dressing after operation showing the sea sponges as they have become molded in place. D, Complete release of the arm has been obtained and a full "take" of the thick split grafts is shown one operation. Jackson extends from anterior

superior spine over flank, chest, axilla and half way down arm. Although none of the scarred surface was removed, it can be seen that the only skin flaps available for closing were small ones over the flank. The triangular inset of skin over the arm is to be noted as important in relaxation. E, Complete function apparent, but close observation shows very tight, heavy scar over hip that makes a general tightness and some hindrance to activity. F, The lack of sufficient skin surface has been corrected in one operation, this has been accomplished by simply opening the scar and dissecting the edges back without sacrificing any surface, and then covering the defect with thick split grafts, as shown.

Fig. 8. A, Deep scars in scar heavily contaminated. Wide open-bite of lower jaw. B, Result of preliminary opening of scars and complete release of the deformity. C, Result of application of split grafts in two operations. Final restoration of contour and smoothness to be gotten with a full thickness graft across the front of the neck as in Figure 6.

Fig. 9. A, Complete fixation of leg to thigh one year after burn. B, Restoration, complete and permanent, after 6 months with thick split grafts. The leg was opened at first operation to within 15 degrees of complete extension. The remainder was accomplished by direct skeletal traction applied by Dr. C. H. Crego. The defect was then covered

with split grafts in two operations. Note healing of donor areas on opposite thigh and abdomen. C, Not triangular insert of graft in thigh; this is shown because of its importance in relaxation. D, This photograph which was taken 8 years later shows that there is complete function and no foot drop.

Over many years observation we have proved in our own minds the superiority of the sea sponge as a medium for obtaining pressure over skin grafts and have preferred to develop its use on a simplified plan rather than search further for substitutes. That the pressure be applied and maintained is the

principle, however, and if it is effected with a medium other than a sea sponge the object has been accomplished.

Fifth. In the repair of late burn contractions, free skin grafts can be used extensively and give permanent bearing surfaces in many instances. They often may be substituted for

a tedious laborious use of pedicle flaps that require multiple operations.

If there are sinuses extending down into scar folds that harbor organisms detrimental to the chance of "take" of a skin graft a preliminary opening is done and sometimes a huge open wound is produced. In the grafting of all contaminated open wounds we use the thick split graft rather than a full thickness graft because of the greater assurance of its "take" in such a field (Fig. 8).

If the late contraction is healed so that a clean operation can be done then the use of a full thickness graft can much more safely be undertaken but even here, in many instances the split graft can be used satisfactorily and may even be required if the area to be grafted is so large that the necessary amount of full thickness skin cannot be sacrificed (Figs. 7 and 9).

One patient in the series has had 178 square inches of skin transferred at one time and 48 square inches at another (221 square inches total or 1,381 square centimeters).

In repairing healed contractures all surrounding skin possible is, of course, utilized. If there is dense scarring with marked contracture, it is seldom that flaps can be turned in from the surrounding area the entire mo-

Fig. 10. A, Hand shown 2 weeks after a mangle burn. B, Two days later after saline soaks, saline jelly dressing and gentle debridement.

bilization being one of dissection and release of binding scars. In old cases in which the scar has been drawn out into a web and there is little or no deformity it is occasionally possible to effect the repair by using the web itself. This is commonly called a "Z" or reversed "Z" plastic, however the openings seldom actually resemble a "Z" and the main point to remember is that the two surfaces of

Fig. 14. Failure of healing over 9 months' period. There is a complete failure of spread of epithelium grossly and macroscopically, but activity is evidenced by a marked piling up of dead cells. This patient was burned 10 months before, had been in bed the entire time and had spent \$1,200 on an one single proprietary ointment recommended for the treatment of burns. He was treated as the patient in Figure 1 with restoration of the open areas on both legs in two operations.

Fig. 12

Fig. 13

Fig. 14.

the web are saved and fitted across each other to obliterate the web. In many cases the use of adjacent flaps or the two surfaces of the web may be combined with free skin grafts to cover remaining open areas. Scar flaps should not be too large because their blood supply may be extremely uncertain (Fig 7).

In some patients who have healing after very widespread burns, there may be no actual deformity but a general tightness of an area with perhaps some limitation of motion of an extremity. These patients frequently need more skin surface, and a release of the general surface tension is effected by simply opening across the tightest portion of the contracted area, allowing the edges to retract, and then filling in the open area with split grafts (Fig 7).

Sixth. Burns of the hands deserve special attention because every effort should be put forth to prevent the deep infection that will so rapidly fix tendons and joints and produce deformities that may never be overcome. For deep losses, the first treatment should be active surgical drainage, active movement should be encouraged, the fingers should be dressed apart and the whole hand kept in position of function. The average burn should be ready for grafting in 3 weeks, if tendons have not been exposed, and, frequently, the single application of a split graft may be all that is neces-

sary. If there has been an extensive deep burn, as soon as sloughed tendons are separated and the granulations are clean it is often advisable to "dress" the wound with a thick split graft so that healing may stimulate activity and joint fixation may be limited, then later any necessary thicker repair can be done (Figs 10 and 11).

Seventh. The rehabilitation of the patient's activities should be started early, if possible even before surgical restoration is started (Fig 3C). Children usually take care of this themselves but guidance in physical and occupational therapy is always beneficial. Burned hands may require special effort and the use of splints, as notably advocated by Kanavel, Koch, and Mason. In all the working contacts with patients, a firmness of purpose should be maintained that will tend to keep the patient's morale on the highest possible level.

Fig. 2. Thyroid cross-graft in dog, 44 days old, low power

described briefly as follows. Under strict surgical asepsis throughout, tissue is removed from the donor minced carefully into tiny fragments, 1 to 1.5 millimeters in diameter, and planted on a coagulated medium such as is used for tissue culture. After a day or two of observation to insure that the cultures are alive and not contaminated they are transferred to new medium containing serum and plasma derived from the intended recipient of the graft. On this medium they are grown for a period of 2 to 4 weeks, being transferred to fresh medium as often as seems desirable. When ready for grafting a small incision is made through the skin of the recipient, at the

axilla or groin and a pocket pushed open by blunt dissection in the areolar tissue near the large blood vessels. The various fragments of graft are picked up on a pipette containing salt solution squirted into the pocket and the small incision sutured. If the grafts take, they grow slowly in size and after a number of weeks or months restore the physiology of the recipient to normal. This technique at present being used represents a development from many experiments in different directions and on many aspects of the general problem, often resulting in failure, but leading on to better ways of attaining the object. It is, of course, subject to further improvement and

LIVING GRAFTS OF THYROID AND PARATHYROID GLANDS¹

HARVEY B. STONE, M.D., F.A.C.S. JAMES C. OWINGS, M.D. AND GEORGE O. GEY, M.D. BALTIMORE

THE last few years have marked a great stride forward in the treatment of disorders due to deficiency in function of the glands of internal secretion. As a result of the discovery of active chemical substances derived from the glands—thyroxin, parathormone, cortin, etc.—the therapy of myxedema, tetany, and Addison's disease has been given a measure of accuracy and directness entirely new. These brilliant achievements of biological chemistry make it possible to supply from without the necessary substances that the body should produce for itself. The obvious next step in the conquest of these deficiency diseases is to restore to the body this power of producing its own needed substances; in other words, to graft into it a living functioning gland to replace the one that has failed. It is the purpose of this paper to report in brief our work in this field, more extensive details having been published elsewhere.²

After several years of laboratory and clinical studies, which began discouragingly enough but yielded increasingly promising results as time went on, we feel justified in saying with out reserve that we believe successful functioning grafts of thyroid and parathyroid tissue can be made from one dog to another and from one human being to another. As evidence of this we submit illustrations (Figs. 1 to 6) showing photomicrographs of tissue removed for study at intervals of 4 weeks to nearly $\frac{1}{2}$ year after cross-grafting. It is clear that this tissue is living, healthy, and apparently functioning. In further evidence we submit the reports on a number of human cases in which there is reason to believe that cross-grafts have been successful.

CASE 1. Graft of human parathyroid tissue into patient with profound typical tetany following thyroidectomy 18 months previously, which was getting worse in spite of treatment. It is now over a year and a half since the graft was done. This patient is clinically well, has passed through normal labor successfully since the graft operation, and has had a return to normal of her blood chemistry.

CASE 2. Graft of human parathyroid tissue into patient with spontaneous tetany, typical and severe. This case also has been completely successful clinically for a period of a year and a quarter, with return of the patient's blood chemistry to normal.

CASE 3. Graft of human parathyroid tissue into patient with postoperative tetany of severe grade. Duration of time since grafting about 5 months. Patient much better, blood chemistry approaching normal. Graft apparently successful and growing.

There have been 2 other grafts of parathyroid tissue: 1 for postoperative tetany and 1 for spontaneous tetany. In the latter case there was some doubt of the diagnosis. The patient was not benefited by the graft and it has not been repeated. In the first of these 2 cases a graft was apparently unsuccessful after 3 months, so that a second graft has been done. It is too soon to say whether this second graft, now about 6 weeks old, will succeed.

CASE 4. Graft of human thyroid tissue for myxedema after thyroidectomy. This patient has received grafts 3 times, some weeks apart, as much more thyroid substance is required for health than in the case of parathyroid grafts. He has improved clinically, has lost 12 pounds in weight, can work and feel well on a fraction of the dose of thyroid extract formerly required, has a higher basal metabolic rate, and is regarded as a partial success. We hope that with the growth of the grafts in time this success may become complete.

We have also grafted thyroid tissue into several children and one adult for conditions of a complicated nature, part of which was apparently due to deficient thyroid secretion, but in none of these cases do we feel that we can claim success for the graft. It is perhaps unnecessary to point out that no type or method of grafting can reasonably be expected to yield 100 per cent successful results, but the evidence herewith submitted from both animal and human cases seems to us convincing that our method has proved that cross-grafting of these two endocrine tissues can be and has been accomplished.

As to the method itself, the details of which have been published elsewhere, it may be

a part in the success of cross-grafting. Young tissue has a greater "growth potential"—a term of unscientific vagueness but clear enough meaning—than old tissue, and when ever possible should be used as the source of the graft. Also, the recipient is in better condition to support and foster the graft if in general good health than if suffering from a variety of disorders in addition to the specific tissue deficiency for which the graft is done. Then there is the question as to whether a graft can be expected to survive unless the host has a physiological need for it. Halsted suggested that such a deficiency was necessary for the success of the graft and this idea has been referred to as "Halsted's law of deficiency." It is perhaps unnecessary to state that complete surgical cleanliness and avoidance of infection is essential to the success of the procedure.

It will be seen that experimental attack upon the problem of cross-grafting and analysis of the difficulties presented have led to the recognition and understanding of some of the conditions that are essential for success. No doubt further study will extend our knowledge and increase our mastery of this important field. The successful growth of mammalian tissue derived from one animal in the body of another, for an indefinite period of time and with preservation of physiological function is a matter of wide biological interest. Its practical implication in the field of medicine and therapeutics need only be suggested. Whether other endocrine tissues can be successfully transplanted by this or some similar method we cannot say. We do feel safe in saying that cross-grafting of thyroid and parathyroid tissues has been accomplished, both experimentally and clinically.

STATISTICAL STUDY OF DISEASES OF THE OESOPHAGUS¹

A. S. MACMILLAN, M.D., BOSTON, MASSACHUSETTS

IN the past 10 years, 1,600 patients or 1 of every 161 who have been admitted to the Out Patient Department of the Massachusetts General Hospital, have come because of dysphagia or some other symptom relative to the passage of food from the mouth to the stomach.

A study of these cases should give a reasonably accurate idea of the relative frequency of the various causes of difficulty in swallowing.

The entire series of cases was studied from the clinical, roentgenographic and endoscopic standpoint.

No demonstrable lesion could be found in 143 patients, or less than 10 per cent of the 1,600 patients seeking relief for dysphagia.

METHOD OF X-RAY EXAMINATION

The type of examination varies with the lesion suspected. It is not sufficient to give the patient barium to swallow and merely observe the patency of the food passage. The reaction of the muscles of deglutition, the tonicity of the oesophagus, the activity of peristalsis, and the presence of stasis must all be noted.

If we are to pick up the early changes in the wall of the oesophagus before the lesion is extensive enough to produce obstruction a very careful examination is necessary.

The procedure we have found most satisfactory is first to fluoroscope the patient while he drinks a thin barium mixture. If this is negative a heavy thick paste is given which travels slowly enough for the entire oesophageal wall to be examined. The patient is fluoroscoped while drinking the barium mixtures, in both the erect and prone positions. If these show nothing the patient is again given the thin barium mixture and after the bulk of the bolus has passed into the stomach a film is taken with the patient in the right oblique position.

If the oesophagus is normal, thin lines will be seen on the film which indicate the normal

mucosal folds (Fig. 1). If the oesophagus does not properly collapse upon itself interruptions or widenings of these folds may be noted. This method was first described by Schatzki in his work on the delineation of the mucosa of the oesophagus in which he was able to show varices, small ulcerations, and infiltrations which are entirely lost if the lumen is filled with barium.

FOREIGN BODIES

The trauma caused by the lodgement or passage of a foreign body through the pharynx or oesophagus is a very frequent cause of dysphagia. Foreign bodies were found to be present in 183, or 30 per cent, of all those who were referred as suspicious. This is one oesophageal condition more common in the first decade of life (Fig. 2).

Considerably over 90 per cent of foreign bodies lodge in the pyriform sinuses or upper third of the oesophagus.

Because the majority of foreign bodies lodge in the upper portion of the oesophagus, our routine procedure is to take a film of the neck in the lateral position before the patient is given any barium (Fig. 3). This will reveal the presence of foreign bodies which usually are considered non-opaque such as chicken bones and fish bones. On the lateral view in the average sized patient the oesophagus and periesophageal structures measure about one-half the width of the trachea.

If the foreign body is not located on the lateral view a search must be made for it with the aid of a heavy barium paste for if present the barium will adhere to it and will not be washed off by subsequent swallowing of water.

We were able to locate all of the foreign bodies in our cases by either the plate or fluoroscopic method.

If there is oedema and scarification of the mucous membrane from trauma in the passage of the foreign body there will be delay in the transit of the barium and a variation from the normal mucosal pattern but one or two swal-

¹Presented in the symposium on "The Oesophagus" before the Clinical Congress of the American College of Surgeons, Boston, October 3-14, 1934.

Fig. 1. Roentgenogram showing barium in the mucosal folds of the normal oesophagus—fine sharp lines parallel.

lows of water will wash off the barium from any such area of abrasion.

When fluoroscopic examination was negative and there were clinical symptoms suggestive of the presence of a foreign body pre-oral examination was carried out which showed that the continued irritation was due to trauma or infection at the site of trauma.

The types of foreign bodies found in these cases, were, in order of their occurrence chicken bones, fish bones, open safety pins, small lead toys, pieces of wood, glass, and a variety of hardware.

CANCER

Of the remaining 878 patients in this series complaining of dysphagia from some cause other than the swallowing of a foreign body, 350, or 40 per cent, were due to malignancy (Table I).

The ages ranged from 30 to 78 years, the greatest number being in the seventh decade (Fig. 4). Men predominate over women 6 to 1.

In this series, malignancy occurred in the oesophagus as follows: upper third, 124 cases, middle third 103 cases, lower third, 132 cases.

Fig. 2. Graph showing the age incidence of foreign bodies in the oesophagus.

Postcricoid lesions are included in the upper third group. These figures are at variance with percentage of occurrences found by other observers.

Where specimens of carcinoma were taken the types were as follows: epidermoid type 152 cases, adenocarcinoma, 28 cases, non classified, 18 cases.

The majority of patients gave dysphagia and not pain as the initial symptom. Pain is apt to be the first symptom, however, if the lesion arises from the deeper layers of the mucosa and causes mediastinal growth rather than extensive obstruction of the lumen.

The incidence of cancer of the oesophagus is low compared with its occurrence in other parts of the body. U.S. Vital Statistics show it to be responsible for 1½ per cent of all of the deaths from cancer (Table II). Watson, at the Memorial Hospital in New York reports 2.5 per cent. Abel reports cancer of the oesophagus responsible for 5 per cent of all cancer deaths.

Cancer of the oesophagus has been well termed the most melancholy chapter in medicine. It is unfortunate that the average duration of symptoms in patients found to have cancer is over 5 months before seeking relief for by this time they are well beyond any hope of surgical removal or cure by radiation treatment. The only encouraging feature of the matter is that less than half of the patients complaining of difficulty in swallowing in the cancer age, have the disease. The other half for the most part, i.e., those who do not have cancer, are completely cured or greatly relieved by surgical or medical measures.

Fig. 9 Web at the mouth of the esophagus opposite the fifth cervical vertebra

by use of his diagnostic bag proves his contentions beyond doubt. There were 101 women and 34 men in the series, or a ratio of 3:1. The average age at first examination was 40.1 years, the age varying from 16 to 68 years. The average cancer age was 59.3 and the average age for polypoid pouches, 63 years.

FIBROSIS OF THE UPPER END

When infection and consequent fibrosis involves the upper third of the esophagus there is a fusiform narrowing but no dilatation above the point of constriction because of the ease with which food can be regurgitated back into the pharynx. We found this condition accounted for dysphagia in 96 or 11 per cent, of our series. The symptoms are usually of some years' standing before the patients seek relief. The onset is so gradual that the patient is seldom able to recollect the probable cause.

This condition occurs more frequently in women than men.

The ages of patients were between 26 and 82 but the greatest number were in the fifth decade of life.

On X-ray examination a thick barium paste will show a smooth fusiform narrowing of the upper end of the esophagus (Fig. 8). The esophagus is not deviated from the midline

Fig. 10 Age incidence of webs of the esophagus in 14 patients.

as it might be by an external pressure, and the mucous membrane pattern is entirely normal.

The condition produces no pain or distress except the inability to swallow a large bolus of food or in extreme cases, even semisolids or liquids.

On endoscopic examination it may be impossible to pass the large esophagoscope and often the medium sized one will not pass through the stricture. The mucous membrane appears perfectly normal and shows no evidence of previous infection. Because of the fibrosis very little relief is to be gained by dilatation. The psychological effect on the patient of the passage of bougies is one of reassurance, and gives the patient a sense of relief although the roentgenological picture remains unchanged.

WEBS

The next most common lesion occurs in the mucous membrane with the formation of partial diaphragms of mucous membrane or webs, with either a central or excentric opening. This type was first described by Mosher in 1917.

It is usually possible to obtain a definite history such as trauma from swallowing a foreign body or superficial ulceration of the mouth or pharynx, followed in due time by dysphagia. These lesions are frequently found opposite cervical exostosis.

The roentgenological picture (Fig. 9) is radically different from that of fibrosis. There is an abrupt, sharply defined narrowing at the location of the web. After passing this point the lumen regains its normal outline. This

Fig. 11. Aneurysm of the arch of the aorta causing pressure on the oesophagus—syphilitic ulceration of the oesophagus is rare.

picture is so typical and definite that there is little chance of confusing it with other lesions.

This condition existed in 114 patients, or 13 per cent. The average age was about the same as that for fibrosis of the upper end. Eighty four per cent of these were females and 16 per cent males (Fig. 10). Patients are susceptible to exacerbations of their dysphagia due to trauma from rough food. The marked relief that can be given by breaking or stretching this thin diaphragm of mucous membrane by use of instruments through the oesophagoscope is spectacular.

EXTRINSIC CAUSES OF DYSPHAGIA

Extrinsic causes of dysphagia occurred in 31 cases, or about 3 per cent.

The oesophagus may be constricted by external pressure along any part of its course. In one series, 25 out of the 31 cases were located in the upper third of the oesophagus. In the neck region the oesophagus is located in close relationship to a number of important structures, which are often the seat of primary or metastatic malignancy such as tumors of the thyroid and larynx and metastatic masses in the glands.

Fig. 12. Lye burns may produce serious strictures at various levels, with normal oesophagus in between. This patient (4 years) had one at the level of the episternal notch and another in the lower third.

In this group of cases we have some of the most interesting diagnostic problems. It is only by the most careful and painstaking work, from a roentgenological and endoscopic standpoint, that external pressure can be differentiated from actual involvement of the wall of the oesophagus such as occurs in cancer arising from the deeper glands of the oesophagus for in such a lesion the bulk of the tumor mass is apt to be in the mediastinum with very little showing on the mucosal side.

Burns. There appears to be a decrease each year in the number of cases of oesophageal burns and resulting strictures from the swallowing of acid or alkaline corrosives. There were 40 such cases in our series, or about 0.5 per cent. They were evenly divided between the sexes.

There are twice as many strictures located in the middle third as in the upper part. This is probably due to the protecting covering of saliva in the mouth and pharynx and upper end of the oesophagus, through which the liquid passes rapidly, there is a normal slowing up of ingested matter at about the level of the arch of the aorta.

When the mucous membrane alone is involved there result thin membranous strictures which simulate the webs so often found

Fig. 13 Age incidence of paralysis of the muscles of deglutition

Twenty five per cent of the stricture cases were of this type. If the mucosa is entirely denuded by the caustic fluid and there is a gluing together of the submucosal structures, there results a tubular stricture varying in length and diameter. Seventy five per cent of the stricture cases had a tubular stricture involving one half or more of the lower part of the oesophagus.

PARALYSIS

Paralysis of the oesophagus is a rare condition and was not encountered in this series, but paralysis of the muscles of deglutition is not uncommon and was noted in 46 patients (Fig. 13). There were 15 males and 31 females, with the average age 47 years.

The symptoms are so difficult to differentiate from those due to obstruction of the upper end of the oesophagus that it seems logical to consider this group of cases in speaking of diseases of the oesophagus.

The paralysis is always of central origin and may be due to any one of various etiological factors: an infection such as poliomyelitis; a localized central hemorrhage, brain tumor, fracture at the base of the skull with hemorrhage, and Parkinson's disease.

The muscles of the tongue may be sluggish and unable either to form the bolus properly or to give it its initial push into the pharynx.

The findings are very striking on fluoroscopic examination. Instead of being assisted by normal muscular action, the ingested material drops by gravity into the pharynx and completely fills up this area. The pyriform sinuses are entirely flaccid (Fig. 14). The oesophagus

Fig. 14 Paralysis of the muscles of deglutition due to cerebral hemorrhage. Note the dilated pyriform sinuses. The lack of motion when the patient attempts to swallow is striking.

does not open to receive the bolus as it normally should and the barium remains in the pharynx until expectorated.

Cases of localized cerebral hemorrhage which presented no other manifestation of their presence accounted for less than half of our cases. The history is characteristic: the condition is first realized when the patient attempts to drink or swallow food and is unable to do so.

After an interval of a few days the patient's ability to swallow returns and the function may be entirely restored. On endoscopic examination with the oesophagoscope, nothing unusual is noted except flaccidity of the pyriform sinuses. There is no evidence of spasm or closure about the mouth of the oesophagus.

POUCHES

Pouches of the oesophagus are rarely recognized during life because they do not produce obstruction and seldom produce symptoms of dysphagia. They comprise less than 1 per cent of our cases.

They are likely to be found during the swallowing of barium in the routine examination of the oesophagus in gastro-intestinal X-ray examination.

Fig. 15. Zenker's pulsion pouch of the lower pharynx, showing barium in the oesophagus, the neck, and the pouch. Symptoms in this case were sensation of lump but little obstruction.

The most common site is the middle third of the oesophagus in the region of the bifurcation of the trachea, and the most frequent type is the traction variety. Traction is caused by the pull exerted on the oesophageal wall by bealing mediastinal glands which are also attached to some less yielding periesophageal structures such as the trachea and dorsal spine. These diverticula are very often conical in shape, although occasionally sacculated ones, which contain food do occur Rokitsansky in 1840 first described the traction type.

The next most frequently described pouch is the pulsion type which occurs in the lower third of the oesophagus just above the diaphragm. Portis reported a case of a pulsion diverticulum which enlarged so much that it produced cardiac embarrassment which was relieved only by washing out the pouch with a stomach tube.

In our series no such severe symptoms were reported but there was substernal distress in 2 cases.

Sacculations of the oesophageal wall may arise above a location of stenosis. Six cases of this type appear in the literature and the seventh case was described by Mosher at the last meeting of the American Bronchoscopic Society.

Fig. 16. Age incidence of pharyngeal pouches.

PHARYNGEAL DIVERTICULA

The first case of this type was reported 170 years ago by Ludlow and since then there have been scores of papers written reporting hundreds of cases. The condition accounted for only 32 cases or about 3 per cent of all of our dysphagia cases.

The severity of the symptoms produced by these pouches is in direct proportion to the size of the pouches.

Various theories have been advanced as to the etiology of the herniation of the mucous membrane through the fibers of the inferior constrictor muscle. Jackson believes there is an inco-ordination in the neuromuscular mechanism which results in a failure of the lower part of the constrictor to open when the bolus arrives at this level, this, momentarily, produces an increased pharyngeal pressure.

The ages of our patients varied from 45 to 83 years and averaged 63 years (Fig. 16). The ages coincide quite closely with the carcinoma cases, which makes the diagnosis of great importance.

In Lahey's report of 21 cases the average was 67 years.

Males predominated over females 4:1. We had 24 men and 8 women.

Diagnosis is made very readily by X ray examination. The pouch in the well developed case appears to be a continuation of the lower pharynx while the mouth of the oesophagus appears as an opening high up on the anterior wall of the pouch. This condition produces a progressive dysphagia which may result in an inability even to swallow liquids. Swallowing motions are accompanied invariably by gurgling sounds. The pouch may become

Fig. 17. Ulcer of the lower end of the esophagus with a typical ulcer fleck, x, in an area of scar tissue at the lower end of the esophagus. Note spasm a short way above the ulcer.

filled up with food or air and produce a palpable swelling in the throat which may cause pressure on the laryngeal nerve.

The X ray findings make any error in differential diagnosis quite unlikely.

The treatment is the surgical elimination of the pouch. If this is impossible the esophageal opening may be dilated; this at least benefits the patient psychologically.

ULCERS OF THE ESOPHAEGUS

Young adults comprised most of our 14 cases of ulcer of the esophagus. The lesion occurred most commonly in the lower third of the esophagus. Clinically the outstanding symptom is the substernal pain accompanied by dysphagia. The pain is apt to be intermittent as is the case in ulcers elsewhere.

The fluoroscopic examination reveals considerable spasm of the esophagus. After the patient is given barium there is a fleck remaining in the ulcerated area. It may be difficult to confirm the X ray findings with

the esophagoscope because of the scar tissue already formed about the ulcer by the time the patient seeks relief.

These ulcers are prone to occur in islands of aberrant gastric mucosa which are infrequently found scattered about the mucous membrane of the esophagus more common in the lower third.

Ulcerations of the esophagus from tuberculosis occurred in but 1 patient in our series, who already had had extensive pulmonary and mediastinal tuberculous involvement. Differential diagnosis of this case was made possible by microscopical examination of a portion of the ulcer.

Syphilitic ulceration is extremely rare. Guisez in 3000 cases found but one of which he could be sure. Less than a dozen have been reported in the literature and there were none among our cases.

THE OESOPHAGUS¹

HARRIS P. MOSHER, M.D. F.A.C.S. BOSTON, MASSACHUSETTS
 Professor of Otolaryngology Harvard Medical School

IT is my purpose to review the work on the oesophagus which has been done in Boston and to give the Boston point of view.

Exostosis and webs of the oesophagus Webs of the oesophagus were first put on record in Boston a good many years ago. The cause of webs was at first indefinite, the only ready explanation being an ulceration of two opposing surfaces of mucous membrane caused by appropriate bacteria. I am excluding of course, strictures caused by caustics. Later it was found that exostosis of the cervical vertebrae was often associated with webs of the upper end of the oesophagus. These spurs can be so sharp as to pierce the oesophagus and give bleeding. The first of the cases was discovered in this way. We all know that exostosis or lipping of the cervical vertebrae is common in the orthopedic clinic, and in the majority of such cases there is no difficulty in swallowing. However, in patients who come to the hospital with difficulty in swallowing, we have found that exostoses are a fairly common cause.

Webs can occur anywhere about the upper end of the oesophagus in the pyriform sinuses where the symptoms are those of a small pouch, that is, the patient regurgitates small amounts of food from time to time and has difficulty in swallowing any large bolus of food. They occur also behind the cricoid cartilage.

The webs are placed so high that the obstruction caused by them causes food and fluid to spill over into the larynx, thus producing violent laryngeal spasm. This makes meal time for the patient with a web a time of terror. Such patients therefore, cut their diet to a minimum and lose weight markedly.

The treatment of the web, especially if it occurs in the pyriform sinus is to put it on the stretch by ballooning it with air and then to bite out a generous piece of it. This is followed by the periodical passage of a bougie.

Occasionally a web may make an almost complete diaphragm back of the cricoid. This

generally has a central opening. Such a web is easily divulsed. I remember one patient who had such a web, who had so much difficulty from it that she had to take all her meals in the bathroom.

There is another type of web, sometimes single and sometimes rather a periesophageal thickening for an inch or more. This is found below the cricoid cartilage. We have known about these webs perhaps for the last 10 years. Dr. Macmillan and Dr. Smyth were the first to focus attention on this type. They are easily dealt with by stretching under ether followed by the periodical passage of a bougie, especially by the passage of the mercury bougie which is safe to give the patient for him to pass on himself.

For a long time we were in doubt as to the cause of such webs but, as I shall show later, we now have abundant cause for them in infection of the oesophagus in acute or chronic disease.

Pouches of the oesophagus I should like first to dispose of pouches which spring from the oesophagus at the bifurcation of the trachea and those which occur at the lower end of the oesophagus. Pouches around the bifurcation are not uncommon. They are generally tuberculous in origin, being due to the healing of a suppurating gland which attaches itself to the wall of the oesophagus. So far as my experience goes they give very few symptoms and require little if any treatment.

Pouches of the lower end of the oesophagus I have seen but few of. I have an autopsy specimen given to me by Dr. McGregor which shows three small pouches in vertical line, one above the other. I have seen one or two single large pouches. My experience with this type of pouch has not been sufficient to discuss them from the standpoint of treatment. They might readily give symptoms of obstruction from their size or from twisting on their pedicle.

Pouches of the upper end of the oesophagus or oesophageal hernia Pouches of this type, of

hemorrhage. At autopsy the bleeding point could not be found. Often it cannot be determined.

Fig. 3 Atrophic curiosis of the liver. The picture shows 1 cysts projecting into esophageal lumen and cysts under mucous membrane. In chronic infection of the esophagus infected glands and cystic gland ducts are common.

Fig. 3

course are fairly common. I believe there is an embryological background to these pouches because they are normal in certain animals, for example the pig. In the pig embryo there are two pouches an upper and a lower. Only the lower however persists. In the embryo of man, in what might be called the pig stage there are two similarly placed pouches. Both however disappear at birth. The function of the pharyngeal pouch in the pig is to house the very large arytenoids peculiar to this animal. The anterior attachment of the esophagus is to the back of the arytenoids in the pig as well as to the back of the cricoid.

Many years ago I found it was common in pouches in man to have the opening of the esophagus asymmetrical, that is, one pyriform sinus is obliterated. This asymmetry of the mouth of the esophagus as I reason it,

puts the tension on the inferior constrictor off center in swallowing and could readily play a part in the formation of the pouch or hernia.

Early in my career I devised an operation for pouch of the upper end of the esophagus, namely I slit the common wall between the esophagus and the pouch. This resulted in immediate relief for the difficulty of swallowing in 6 such cases operated on but the seventh was a tragedy by infection of the mediastinum followed by sloughing of the common carotid. This naturally led to the abandonment of the procedure. For a good many years now I have been referring such cases to Dr. Lahey for the two-stage external operation under novocain. My feeling is that the problem of dealing with this type of pouch is successfully settled. It is a great comfort to have it so settled. This I feel is due largely to

Fig. 4 Atrophic cirrhosis of the liver. The illustration is a cross-section of the oesophagus shown in Figure 3. The oesophagus is riddled with cysts.

Dr Lahey Now that we have Dr Cburchill at the Massachusetts General Hospital who is specializing in chest and neck work, patients suffering from such conditions are naturally referred to him.

Strictures of the oesophagus I have a little to add as to the treatment of such cases. As we know they are more commonly caused by the swallowing of caustics generally one of the commercial washing powders. Owing to legislation originated by Dr Chevalier Jackson washing powder containers dispensing sodium hydroxide are required by law in many states to be labeled *poison*. The public has been educated to the danger of these powders and lye strictures are becoming less common. In a desperate case the best procedure is to put a feeding tube in the stomach and to have the patient swallow a string to be used for retrograde bougienage. Of late I have been using fluoroscopic dilatation of narrow strictures with metal tipped bougies. This is a dangerous procedure and is used only in tight strictures which have to be picked apart slowly and brought to a sufficient size to allow the patient to swallow the string. I have lately had 2 such cases. Dilatation was begun with the bougie tipped with a flexible spiral wire finder. Under the fluoroscope, I found it possible to pick my way through these two strictures, one 4 and one 6 inches in length.

Fig. 5 Old peptic ulcer followed by obstruction and perforation. The section shows dilated gland ducts and chronic infection of the glands. x Lymphocytes in glands.

Foreign bodies As you know almost every type of small hardware finds its way at times into the oesophagus. With the insane sizable objects like forks or spoons occasionally are swallowed. The great point about foreign bodies is to remove them without lacerating the oesophagus because given the right bacteria the posterior mediastinum infects more readily even than the peritoneum or the dura. Every oesophageal examination every passage of a bougie with or without ether, is a potential tragedy. The only foreign body I shall speak

about is the open safety pin point up. The first safety pin closer I invented years ago after a tragedy following the attempt to remove a very large safety pin, almost a blanket pin from the esophagus of an adult. This closer has been modified and its grandchild is now in successful use in this hospital. The youngest child from whom I have removed a safety pin was 4 months old. In dealing with an open safety pin, point up select the safety pin closer which appeals to you—there are a number of good ones on the market—practice

with it outside the body and then under the guidance of the fluoroscope close the pin and remove it. If this cannot be brought about speedily, the thing to do in my opinion, is to put your pride in your pocket and push the safety pin into the stomach. A try of course can then be made, after the fashion of Jackson, to close the pin in the stomach. Again if this is not quickly successful, the pin should be left to nature. For the first 48 hours it should be watched by the fluoroscope or X ray plate to see that it is moving. If it halts, it generally

Fig 9.

Fig 9. The first photograph shows a specimen from a normal oesophagus. The specimen shows the normal amount of connective tissue. The largest amount is between the muscularis mucosa and the circular muscular layer. If the muscularis mucosa is absent, the connective tissue is subepithelial. In this specimen there is a small amount of connective tissue between the epithelium and between it and the muscularis mucosa. There is a small amount between the circular and longitudinal muscular layers. The greatest amount is between the muscularis mucosa and the circular muscular layer. Outside the oesophagus, there is also much connective tissue, normally. This is not shown in the section.

Second photograph. Autopsy diagnosis chronic cholecystitis and cholelithiasis and icterus. The specimen of the oesophagus was 11 inches long and bile stained throughout. In the lower third, there were a few cysts in the vertical rugae. The photomicrograph was taken from a section 1 inch above the cardia. The section shows a great increase of connective tissue. The subepithelial connective tissue is increased in amount and is oedematous. The subepithelial vessels are enlarged. The circular muscular layer is almost obliterated by fibrous tissue. Other sections show enlarged and infected gland ducts. All the sections show chronic infection. This specimen is a striking example of fibrosis of the terminal portion of the oesophagus associated with chronic infection of the gall bladder.

Fig 10

1 Epithelium 2 muscularis mucosa 3, superficial layer of connective tissue 4 circular muscular layer 5, connective tissue 6 longitudinal muscular layer 7 periesophageal connective tissue 8 fibrous tissue nearly replacing circular muscular layer

stops at the pylorus sometimes straddling it. We had two instances of this. When it was recognized the pin was removed by opening the stomach. Usually the pin leaves the stomach fairly promptly and within a week it is found in the bedpan. I have personal knowledge—and this happened outside the hospital—of but one case in which a safety pin, after it had left the stomach, perforated the intestinal wall and caused a fatal peritonitis.

Carcinoma of the oesophagus. There are 2 types of carcinoma of the oesophagus: epidermoid, or squamous cell carcinoma, and adenocarcinoma. Adenocarcinoma is less common and is found usually at the lower end of the

oesophagus. I have tried all the usual procedures in connection with cancer of the oesophagus, from curettage to X-ray and radium. All my life I have been pursued by cancer of the oesophagus and I have always said the I stand as helpless before it today as I did at the beginning. Within the past 6 months, however, there have been some hopeful results at our hospital with heroic doses of X-ray. In epidermoid carcinoma there have been one or two promising results. No results have been obtained in adenocarcinoma.

I feel that the thoracic surgeon might be called the liver approach. The end of the oesophagus is likely to

Fig. 11. Old peptic ulcer followed by obstruction and peritonitis. This section is taken from the fibrous constriction at the lower end of the oesophagus. It shows almost no muscular tissue. 1. Fibrous tissue.

best result from surgery. I expect that the thoracic surgeon will add to his accumulating honors by reporting successful operations of this character in the near future.

Plummer Vincent syndrome. The medical service of the hospital has referred a few patients labelled as having the Plummer Vincent syndrome. Such patients did have a smooth tongue, anemia and a slight difficulty in swallowing. In all of them a careful oesophageal history revealed signs of oesophageal obstruction for a considerable time that is, from 1 year to 4 or 5 before the appearance of the anemia. The X-ray picture in these patients showed slight web of the oesophagus. This was confirmed by examination with the oesophagoscope. As far as the cases go which I have seen I feel that the primary and essential lesion was a web of the oesophagus, the anemia being secondary. I have not seen enough cases to be convinced that the disease called Plummer Vincent syndrome is an actual medical entity.

Hernia of the fundus of the stomach through the oesophageal opening of the diaphragm was first reported, I believe, by the late Dr. Morrison of Boston. He is the second Boston man

to become a martyr to X-ray burns. Oddly enough the first one, Dr. Walter Dodd, Dr. Morrison assisted for years. In order to make a diagnosis of this condition the patient has to be examined in the prone position. Most of our oesophageal examinations are made in the upright position. I have seen but few of these cases and know them mostly second hand.

Up to within a few years ago the common pathological conditions found in the oesophagus were strictures due to caustics, malignant disease, and pharyngeal pouches. In the literature there were references to acute infection of the oesophagus generally of unknown origin and to ulcers. Tuberculosis was mentioned occasionally but not often so was syphilis. I have never seen a case of syphilis of the oesophagus. I have seen only 2 or 3 ulcerations which were probably tuberculous. I have seen a few cases of pemphigus.

Ulcer of the oesophagus. Speaking of ulcer of the oesophagus, there is no reason why ulcer should not occur especially at the lower part since this is histologically comparable to the upper end of the stomach, and ulcers of the fundus of the stomach are common. Years ago I learned to be suspicious of my findings with the oesophagoscope at the lower end of the oesophagus. It is hard to be sure of what

Fig. 12. Central pneumonia. The section shows three thrombosed veins. 1. Thrombosed vessels.

Fig. 13. Infectious thrombophlebitis. The first photograph shows three peri-oesophageal abscesses. The second photograph shows an abscess in the oesophageal wall near the peri-oesophageal abscesses, 1

you see at the end of a 16 inch tube, especially when, in looking for an ulcer, you have to use it edge on. This makes me doubt the frequency of true ulcer as I find it reported in the literature. The slightest maladjustment of the end of the examining tube causes the mucous membrane to bleed and the bleeding point may be easily mistaken for an ulcer. Frankly I have seen very few ulcers of the oesophagus of which I could be sure. As I said a moment ago, the natural place for ulcer of the oesophagus is at the lower end (Fig. 1). If in a patient with ulcer symptoms the X ray picture shows a small pea like protuberance in this locality, I feel it is reasonable to assume that this is an ulcer. We have only 3 or 4 cases with such a finding.

Cirrhosis of the liver and the oesophagus. It has long been known that cirrhosis of the liver interferes with the venous drainage of the oesophagus and leads to dilatation of the oesophageal veins. In some instances the veins are so large that they will show in the X ray film. Such cases may be associated with hæmorrhage which at times is fatal. It is not necessary, however, that the dilatation of the veins be of the extreme type for hæmorrhage to

occur. The pathologists say that it is often hard to find the source of the hæmorrhage in fatal cases. Figure 2 is of a case in point. Not only are the veins enlarged in cirrhosis of the liver but the ducts of the glands become cystic and are often infected. I have a number of specimens showing the oesophagus riddled with small cysts and 2 or 3 specimens in which there were single cystic enlargements fully a centimeter in either diameter (Figs. 3 4 5).

Danger of oesophagoscopy. For years I have maintained that every examination of the oesophagus even the simple passage of a bougie is a possible tragedy. I have had a few tragedies with both procedures. The general impression is current among the medical staff of our hospital that oesophagoscopy is too dangerous a procedure and they do not feel safe in referring cases for oesophageal examination. Those of us who are doing oesophageal work have known all along that our percentage of tragedies was low. However, in order to have the actual statistics I had them looked up. During the past 12 years, there have been 938 oesophageal examinations with the oesophagoscope. There have been 19 mortalities associated with this examination and probably

Fig. 14. Old peptic ulcer followed by obstruction and peritonitis. The photomicrograph shows dilated glands in the oesophagus with marked infection. The high power view showed definite abscess in the mucosa with marked infection throughout the whole area.

due to it. This makes a mortality rate of a little over 150 per cent. I defy any medical man who is not simply a bedside watcher to show me any surgical procedure with a smaller mortality rate.

The cases of stricture of the oesophagus numbered 204, with 6 mortalities reported in this group. Webs of the oesophagus numbered 79 with 1 mortality. Carcinoma of the oesophagus numbered 247, 9 mortalities. Foreign bodies of the oesophagus including all kinds, simple and the most difficult, numbered 285 with 2 mortalities. Cases of cardiospasm numbered 33 with 1 mortality.

TABLE I.—MORTALITY RATE FOR OESOPHAGOSCOPY

Oesophagoscopies	October, 1917 to August, 1918	Mortalities
Stricture of oesophagus	204	6
Web of oesophagus	79	
Carcinoma of oesophagus	247	9
Foreign body of oesophagus	285	2
Cardiospasm	33	1
Total	938 (15 + %) 19	

Remove the carcinoma cases (these are fatal cases anyway) and the percentage is less than 1 per cent.

The oesophagus at birth. I have specimens showing that the oesophagus can be markedly infected at birth. I have found 1 case of ulcer thus occurred at the lower end. Also I have 2 or 3 specimens showing a backward bend of the terminal portion of the oesophagus. In other words, there is abundant proof that the

oesophagus can be in trouble before birth. In a children's hospital it is not uncommon to find malformations of the oesophagus due to congenital syphilis. In our hospital we do not see this type of case. Speaking of children brings up the question of a congenitally short oesophagus. Here again I have no experience with children to base my opinion on. However I do know that in the adult the oesophagus can be shortened by the contraction of adhesions caused by a lye burn in childhood or to be specific, a young woman of 20 had a lye burn of the oesophagus at 2 years of age. At the present time, that is, after 18 years, the stomach is pulled into the chest a third of the distance to the arch of the aorta. At birth it is not uncommon to find hæmorrhage into the oesophagus or marked periesophageal hæmorrhage. The pediatricians maintain that this is due to asphyxia occurring during delivery. I have a feeling, however, that it may be associated with sepsis.

Hæmorrhage into the oesophagus. Periesophageal hæmorrhage is not uncommon in the adult. Hæmorrhage into the oesophagus itself also is not rare. I have 1 specimen in which hæmorrhage into the lower end of the oesophagus was sufficient to rupture both layers of muscle. This was a septic gall-bladder case and I have it in mind that the hæmorrhage harks back in this case to sepsis. (Figs 5 and 6.)

Narrowing of the cardia at birth. I have 3 specimens showing marked narrowing of the cardiac end of the oesophagus at birth with dilatation of the oesophagus about the strictured area. Congenital narrowing of the pylorus has long been known. If the operative procedure for the treatment of congenital stenosis of the pylorus should in any instance prove unsuccessful the surgeon has a ready alibi in the possible presence of a narrowing at the cardia as well as at the pylorus.

Myoma of the oesophagus. Myoma of the oesophagus was new to me up to a few years ago. I have lately accumulated 4 or 5 specimens of this condition. It has been reported in the literature but is exceedingly rare. It is important only from the fact that should the myoma grow after the fashion of these tumors in the uterus it could easily be a cause of trouble. (Fig 7.)

Fig. 15 Atrophic cirrhosis of the liver. The vessels throughout this oesophagus were greatly dilated. The photomicrograph shows a gland which is adherent to the oesophagus. Over this the oesophageal muscles are replaced by fibrous tissue. On the opposite oesophageal wall, the enlarged superficial vessels are surrounded by dense fibrous tissue. 1 Muscle fibers 2 fibrous tissue 3 gland.

Fig. 16 General peritonitis. The photograph shows many patches of exudate.

Septa of the oesophagus A number of years ago I came across examples of partial transverse septa in the lower portion of the oesophagus. I found them only in the adult. They weaken the oesophagus by making a band of scar tissue partially encircling its lumen. I feel that they hark back to infection spreading along the sheaths of the blood vessels from without in. When they are multiple they divide the oesophagus into segments. Their clinical importance lies in the fact that if they engage the point of a bougie or the end of the oesophagoscope they might easily lead to a rupture.

Infection of the oesophagus in acute and chronic disease Early in my career in dealing with cases of so called cardiospasm I became convinced that spasm played a minor part in cases as they came to our hospital. Under the fluoroscope there are generally no signs of peristalsis, therefore, of course no signs of spasm. In the last 10 years Dr Macmillan and I cannot have seen more than 8 or 10 cases in which spasm was a prominent feature. As I have just said, in most of our cases there is no spasm demonstrable. Examination with the oesophagoscope convinced me that many of these cases were really cases of stricture of the terminal portion of the oesophagus. I found that in many of them the stricture consisted of only a slight gluing together of the

vertical folds which are so prominent in the terminal portion of the oesophagus. At first I was at a loss for a cause of these strictures. Then I began to find in autopsy specimens, especially in specimens of gall bladder infection, that the terminal portion of the oesophagus was infected and fibrosed. One striking instance of this is shown in Figure 8. I have not had many autopsy specimens from patients who died of cardiospasm. My friends however, in different parts of the country have contributed a few so that including a case or two of my own I have been able to examine the oesophagus in some 5 cases. In all of the specimens there was a fibrosis of the terminal portion of the oesophagus associated with a disorganization of the musculature. The oesophagus above the terminal portion, that is, in a long standing case showed fibrosis also but to a less extent. This made me feel that the essential lesion in cardiospasm is a fibrosis of the terminal portion of the oesophagus due to infection from neighboring organs, especially the gall bladder and the thorax. (Figs 9 and 10)

The frequent finding of webs at the upper end of the oesophagus and below the cricoid cartilage not associated with cervical exostosis left me in the dark as to their cause. Then came the finding that the oesophagus can be infected in acute disease as well as in chronic—

Fig. 7 General peritonitis. The photomicrograph shows an infected superficial ulcer over which there is a marked exudate.

for example in pneumonia pyæmia and chronic nephritis (Figs 11, 12, 13). A further finding was that in chronic infection of the œsophagus and in the degenerative diseases like arteriosclerosis there is marked increase

Fig. 18 Mesenteric thrombosis. This photomicrograph shows a superficial ulcer of the œsophagus. Other sections showed chronically infected glands. In one section there was a blocked and infected duct which had broken down into an abscess.

in the fibrous tissue of the œsophagus, in many cases amounting to an obliteration of parts of the circular or longitudinal muscular layers. It became evident, therefore, that the œsophagus could be infected not only from without and from the blood stream, but probably could be infected from within by way of the glands. In other words, it is extremely common in chronic infection to find an increase of the subepithelial connective tissue of the œsophagus. These findings, plus the fact that periesophageal hemorrhage and hemorrhage into the musculature of the œsophagus occur give I feel abundant cause for webs or strictures of the œsophagus at any part of its course. It becomes unnecessary therefore, to rely on spasm especially at the lower end of the œsophagus as the chief cause of œsophageal obstruction (Figs. 14, 15, 16).

Cardiospasm or fibrosis of the terminal portion of the œsophagus. I feel, as I just said that spasm plays but a minor part in the condition commonly known as cardiospasm. I have had a sufficient number of autopsy specimens to prove to my satisfaction that the essential lesion is a fibrosis of the terminal portion of the œsophagus in the region of the

Fig. 19 Acute infection. The photomicrograph shows that the epithelium is lacking. In the subepithelial tissue the fibers has in places turned to fibrous tissue. 1. Fibrous; 2. longitudinal muscle layer; 3. solitary follicle; 4. fibrous tissue; 5. circular muscular layer.

crural canal. The obstruction may be initiated by a fibrosis of the edges of the crura, a perioesophageal fibrosis in the crural canal or a fibrosis in the oesophagus itself confined to the subepithelial connective tissue or a fibrosis involving one or both of the muscular layers and destroying the greater part of the musculature.

Next in importance to the fibrosis which is due to infection of neighboring organs, is a backward bend of the terminal portion of the oesophagus. I have mentioned finding this at birth. I cannot give the cause unless again it is an old inflammatory process. When fibrosis of the terminal portion of the oesophagus has existed for any considerable time this backward bend or trapping of the oesophagus is a constant finding and it is this backward bend associated with a vertical twist of the oesophagus which keeps the obstruction going. For instance, after the terminal portion of the oesophagus has been dilated a few times the patient has marked relief, but under the fluoroscope there is practically always a fluid level at or near the arch of the aorta. This

Fig. 21. Coronary thrombosis, chronic infection. The photograph shows a loss of epithelium in the lower third of the oesophagus. The microscopic slides showed an infiltration of the lymphocytes where the epithelium is lacking. The oesophagus, therefore, shows chronic infection.

Fig. 20. Acute infection. The photomicrograph shows that the epithelium is lacking. There is a subepithelial thickening due to a deposit of fibrin. Two gland ducts, 3, show hypertrophy of the epithelium which occludes one and almost occludes the other. 1, Fibrous tissue; 2, longitudinal muscle; 3, gland ducts; 4, dilated ducts; 5, circular muscle.

of course, is due to continued obstruction. Both Dr. Macmillan and I firmly believe this recurring obstruction is due to the backward bend just mentioned plus a vertical twist. Spasm, of course, would do the same thing if

Fig. 22. Arteriosclerosis, chronic infection. The section shows a slight infiltration of Auerbach's plexus with lymphocytes. I have found a similar infiltration in this series of specimens, perhaps five or six times. I have not yet found an infiltration with polymorphonuclear leucocytes. I still think that involvement of Auerbach's plexus in cardiospasm is a secondary and not a primary affair.

Fig. 23, above. Passing the diagnostic bag. The position of the instrument table, the patient and nurse, and the vertical fluoroscope are shown.

Fig. 24. Passing the diagnostic bag. In the first figure the roentgenologist is about to take a plate. In the second figure the diagnostic bag is in place, the assistant is inflating it, and the operator is watching the dilatation on the fluoroscopic screen.

we could find evidence of it in these cases. As I have said before we have been unable to do this (Figs. 17, 18, 19).

When the diaphragm descends and the esophagus is watched under the fluoroscope it is seen to close. It opens when the diaphragm ascends. The point of closure is always at the beginning of the crural canal. This is the place where the diagnostic bag uniformly shows a fibrotic narrowing. In these cases the X-ray film shows at the beginning of the crural canal either an annular constriction which is more marked on the left than on the right due to the large left crus, or it shows a waist-like constriction.

Examination of the esophagus by fluoroscopic sight. After modifying the Sippy bag by stripping it with barium lines and tipping it with a spiral wire flexible finder it became possible not only to examine the terminal portion of the esophagus by sight but to dilate it by sight. The modified Sippy bag can be used for diagnostic purposes and for dilating the esophagus. In my work this instrument has proved to be the greatest advance in esophageal manipulations which I have tried for the past 10 years.

Barium pictures of the lower end of the esophagus. In the typical case of fibrosis of the terminal portion of the esophagus, this organ is

seen to come to an awl like point at the beginning of the crural canal, and seems to be absolutely closed. However in the great majority of cases the flexible tip of the diagnostic bag, which has a diameter of a *No 30 French*, with a little manipulation can be made to pass into the stomach. Furthermore in a certain number of cases a mercury bougie which is half again as large as the tip of the flexible finder will pass into the stomach. When I first came upon these findings they were rather startling to me. It is because the larger mercury bougie will pass in so many cases that many medical men hold to the spasm theory as a cause of the condition under discussion. However, if the diagnostic bag is passed in these cases as I have done repeatedly, the plate will show the typical fibrotic narrowing (Figs. 20, 21.)

Treatment of fibrosis. The first procedure after gaining the patient's confidence and getting a preliminary X ray plate, is to pass the diagnostic bag to locate the position of the fibrosis and its amount, and to begin the dilatation. In the usual case 3 or 4 dilatations with a pressure of 3 or 4 pounds at intervals of 2 or 3 weeks, will dilate the fibrosis sufficiently to do away with most of the difficulty in swallowing. When the oesophagus can be dilated to normal that is, up to 1 inch, under the pressure given above, the patient is instructed in the use of the mercury bougie and given one to use himself. In the beginning he generally passes the bougie once a day for a month or two and then gradually lengthens the interval. At first when the patient returns for observation and dilatation there is a fluid level at or near the arch of the aorta, showing that the backward bend plus the vertical twist keep up a certain amount of obstruction. A time comes, however when the effect of the dilatation is permanent and the fluid line disappears. In other words the patient comes in for examination with the oesophagus empty. The majority of cases of fibrosis of the terminal portion of the oesophagus can be successfully handled in this manner. When the condition has existed for as many as 30 years (I have such a patient), the oesophagus is markedly dilated and sags decidedly to the right. The terminal portion bends to the left and lies

horizontally on a flat motionless diaphragm. Just before the oesophagus gains the stomach it bends in goose neck fashion back to the right. In other words the oesophagus has two bends. These cases are dangerous to handle with the bag unless extreme care is used. Often it requires great patience to coax the spiral wire finder into the stomach and in some of the cases the fibrotic opening is so narrow that it will admit only the tip of the bag. In these old cases the oesophageal wall is extremely thin so that it is better, at least for a novice to have the patient swallow a string and to use this as a guide to pass the bag. Furthermore, in these cases unless the bag can be manipulated into the stomach either by sight or by the help of a swallowed string, I feel that the operation of anastomosing the terminal portion of the oesophagus to the fundus of the stomach is the coming method of treatment. A number of such operations have been done in England and at least 2 in the Massachusetts General by Dr Churchill. The difficulty in all work on the lower end of the oesophagus by the abdominal route up to the present time has been the inadequate and restricted surgical approach. However, by turning up the left lobe of the liver and mobilizing the lower end of the oesophagus Dr Churchill demonstrated that the operative field can be much enlarged, and in the case in which I saw him use this procedure he had ample room to work. This is a great advance in operative technique.

Oesophageal instruments. In speaking of safety pins I have mentioned the safety pin closer which originated here in Boston. It is one of the most positive that has yet been devised and is practically fool proof. The oval oesophagoscope with the ballooning attachment also originated here; this too appeared a good many years ago. It is in constant use today. It is a great help in locating the opening of eccentric strictures and in making small new growths of the oesophagus visible. It is also useful in locating the oesophageal opening at the cardia in advanced cases of fibrosis where the oesophagus bends markedly to the right and is greatly dilated so that the folds make it very hard to find the opening into the stomach until the oesophageal walls are put on

the stretch by ballooning. I have already spoken of the diagnostic bag striped with bari-um and tipped with the spiral wire finder. By introducing the bag under the fluoroscope we can watch the finder turn dead man's curve and see when the end of it enters the stomach. The present finder has a very heavy end which more or less automatically falls into the stomach. It is only when the finder is well in the stomach, of course, that it is safe to carry the bag down.

The hollow bougie with the flexible metal staff is the most recent addition to my armamentarium and my feeling is that it will prove one of the most valuable, especially for those who are not doing many cesophageal examinations. It occasionally happens, in beginning the treatment of a patient with fibrosis, that the finder will readily enter the stomach but the tip of the diagnostic bag will not. In these instances the hollow bougie with the flexible metal staff is especially useful. Suppose the cesophagus is markedly bent to the right in such a case the flexible bougie fails to follow this bend. Without the flexible finder it is very dangerous to pass this curve. The flexible finder will take the curve readily and you see it make the turn under the fluoroscope. When the finder has been manipulated into the stomach the flexible metal staff is inserted. This straightens out the bend of the flexible bougie and the operator has a straight and safe shot through the cardia. Bougies of any size can be fitted with the flexible finder so that after the fibrosis has been dilated sufficiently with the diagnostic bag bougies of large size equipped with the finder can be passed in place of the bag.

Speaking of dead man's curve, this is the place where the tip of the ordinary flexible bougie will not make the turn, hence it is the favorite site for perforations. The blind passage of the old fashioned elastic bougie has been accountable for many deaths and since the perforation almost always occurs at the point just mentioned this place has been aptly named dead man's curve.

Metal tipped bougies. Recently I have had two desperate cases in which the cesophagus was strictured to the diameter of a thread for about 4 to 6 inches. The attempt to pass a

thread in each case failed. Examination under ether gave the location of the cesophageal opening which in both instances was eccentric and at the bottom of a sizable pouch. It was not justifiable to do more under ether than locate the cesophageal opening and to find its size. The attempt to pass a bougie would probably have resulted in a fatality because the operator could not tell where the far end of the bougie was going. Under the fluoroscope however a small bougie with a small flexible spiral wire finder ending in a small olive was inserted in the strictured cesophagus making a small gain each time. This was always done under the guidance of the fluoroscope. It is a nerve-wracking and dangerous performance. In both of these patients the bougie finally picked its way into the stomach, and then the swallowing of a thread was successful. Both patients were being fed through a gastrostomy fistula. Following the successful introduction of the thread, retrograde bougenage was carried out. At the present time a No. 30 bougie passes in one case and a No. 28 in the other.

SUMMARY

In addition to the old finding that fibrosis of the cesophagus, especially of the terminal portion is the result of infection from contiguous organs, it has been shown that fibrosis of isolated areas is fairly common especially in such chronic infections as arteriosclerosis. In infections of the blood stream the cesophagus is often involved to the extent of ulceration. In acute infections (pneumonia) the cesophagus may be infected. Chronic infection as shown by an infiltration of lymphocytes under the epithelium and in the glands and about the gland ducts, is also common. Dilatation of the subepithelial blood vessels is an almost invariable finding in diseases such as cirrhosis of the liver which impede the venous circulation. I have stated in previous papers that cirrhosis of the liver and infection of the gall bladder are among the chief causes of infection of the cesophagus. As autopsy specimens of these conditions accumulate this fact is becoming more and more evident. Hemorrhage into the muscular layers extensive enough to disrupt them may occur when there is back pressure on the cesophageal ves-

sels. The glands of the oesophagus are especially liable to infection, and are probably the chief route by which the oesophagus is infected from within. One form of solitary follicle is simply a collection of lymphocytes following a gland duct to the surface. To recapitulate the oesophagus can be infected from within

and from without, and is often infected in both acute and chronic disease. In the oesophagus fibrosis follows infection, as it does in other organs of the body. As the oesophagus is so frequently infected, there is abundant cause for strictures or fibrosis to occur in any part of this organ.

OESOPHAGEAL SURGERY¹

EDWARD D. CHURCHILL, M.D., BOSTON, MASSACHUSETTS
From the Surgical Services of the Massachusetts General Hospital

SURGEONS are fond of referring to the oesophagus as one of the "last frontiers of surgery" and are apt to imply that its conquest and development lie "just around the corner." Our profession does not retire from marginal lands as easily as the political economists do, or the quest would have been abandoned long ago. Fortunately we have yielded a 99 year lease on the "fishing" and 'film' rights in this territory to an energetic group of specialists, and as the previous papers attest the fishing has been good. The surgeon who professes any interest in the furtherment of knowledge concerning diseases of the oesophagus should either "fish or cut bait" so let us "cut bait" for a few moments and review the results of a limited personal experience in this difficult field.

CARCINOMA

The challenge of malignant disease has been second only to the exigency of wounds of battle in leading the surgeon to extend the boundaries of his science. Nearly every surgeon of experience has considered the problem of carcinoma of the oesophagus and many have tried out their ideas at the operating table or in the experimental laboratory. It is needless to recount the successes—they are so few that they are known by name as 'Torek's case' or 'Eggers' case.' The most recent is 'Turner's case' (8). I shall briefly state my own disappointing experience with the operative treatment of carcinoma of the oesophagus.

Two patients with hypopharyngeal carcinoma (Trotter's female type) have been operated upon by the lateral approach and the oesophagus reconstructed by a skin flap after the method of Trotter. In both instances the continuity was re-established as evidenced by bougienage and the incision completely healed. Following the operation neither patient could swallow anything except small amounts of liquid, due to the destruction of the muscles at the pharyngo-oesophageal junction that play so important a rôle in the mechanism of swallowing. One patient died of recurrence in less than a year, and the other is now in a terminal stage with cervical lymph node involvement. Although the exposure seemed adequate at the time it is probable that the transthyroid approach described by Orton may be more satisfactory. The failure of the patients to regain the function of swallowing after such an elaborate plastic procedure is disheartening.

The tumors of the middle third of the oesophagus that I have explored have invariably proved inoperable.

In my opinion tumors of the lower third of the oesophagus, other things being equal, offer the best opportunity for successful radical surgery. Again, several have been explored and found inoperable. In two instances, however, the procedure described by Sauerbruch was found thoroughly practical. Nevertheless, both patients died of mediastinitis, one on the tenth day and the other on the second. This operation entails an

Fig. 1. Successful steps in the treatment of a severe lye burn of the esophagus and stomach.

extrapleural approach with the stripping of the diaphragmatic pleura from the muscular layer of that organ. After exposure and mobilization of the growth the diaphragm is cut radially to the esophageal hiatus and the stomach drawn upward into the retropleural space. After the esophagus is severed at the cardiac orifice and the stomach is closed the segment of the esophagus containing the growth is devitalized by a crushing clamp and tight ligature and implanted in the stomach by a modified Witzel procedure. The bulbous growth placed in the lumen of the stomach serves temporarily to ease any undue tension on the suture line and is ultimately digested by the stomach juices. While the operation appears to be a practical one and the exposure excellent and not overly difficult, the operation is probably too extensive when carried out as a single stage procedure.

Patients with carcinoma at the lower end of the esophagus should almost invariably be subjected first to a laparotomy since not infrequently the growth involves the cardiac end of the stomach, the adjacent lymph nodes and frequently the liver. At this stage a gastrostomy may be performed if the growth is inoperable. I would propose therefore, that a laparotomy precede the operation described above and if no intra-abdominal extension of

the disease is found that the cardiac end of the stomach be mobilized by cutting the left gastric artery and the gastrophrenic omentum—a maneuver that is difficult from the retropleural approach. A jejunostomy rather than a gastrostomy may then be performed and the remainder of the operation described above be carried out at a second stage.

As an alternative we must consider in this type of growth the 'pull through' method that has now been successfully performed by Mr. Grey Turner (8). It carries the disadvantage of requiring the construction of a subcutaneous esophagus, but may very well prove to have advantages that outweigh this factor.

STRICTURES

The construction of a new esophagus from the skin of the thorax by the method of Rovsing (5) is a surgical feat that will almost certainly have increasing use in the future. It has been described chiefly in connection with impassable lye strictures but also finds application following resection of the esophagus for carcinoma. Although I have not had the opportunity to complete this operation, the following case history shows the circumstances under which it may be applicable. It also illustrates the complications that may result from extensive chemical injury to the stomach and a method of operative relief.

(1521 L.G. (Fig. 1). On October 10, 1931 a housewife, aged 31 years, accidentally swallowed a cup of lye solution. Three weeks later she was referred to the Eve and Ear Infirmary at which time she was able to take only small amounts of water and milk by mouth. Under observation she showed a rapid and progressive loss of weight and developed neurological symptoms attributable to deficient diet.

On November 21 esophagoscopy was performed by Dr. Tobey. The mouth of the esophagus was found closed by fresh, fibrous adhesions preventing the passage of the esophagoscope. The smallest esophageal bougie (No. 15) could not be passed.

On December 10 laparotomy was performed with the intention of establishing a gastrostomy. The stomach was found to be small, oedematous and adherent to the pancreas. The thickening and induration of the stomach extended downward from the cardiac orifice and included the pylorus and the first portion of the duodenum. There were many fresh adhesions from a perigastric inflammation. An incision was made into the stomach just above the pylorus and the wall was found to be 1 centimeter in

thickness. The layers of the gastric wall could not be identified. The stomach itself contained brown foul smelling fluid similar to that which the patient had been expectorating. A No. 24 T tube was inserted, one end extending upward to the cardia and the other through the pylorus into the duodenum. After a very stormy course the maniacal symptoms arising from the deficient diet subsided and the patient's condition improved.

X-ray studies on December 30 showed almost complete obliteration of the esophagus below the larynx, a small area of intact stomach at the cardiac end, and a free flow of barium into the duodenum through the T tube. On January 19 the patient was able to swallow 3 yards of silk thread. This could not be recovered through the T tube so the tube was removed bringing the end of the thread with it. An attempt was made to reinsert a catheter into the duodenum under the guidance of the fluoroscope but was unsuccessful.

On February 9 a No. 18 French bougie was passed through the gastrostomy opening to the mouth. Increasing difficulty was found in retaining the gastrostomy feedings and the capacity of the stomach seemed to be not over 3 ounces. During the next 2 weeks the patient lost ground steadily apparently due to increasing pyloric obstruction.

On March 3 laparotomy was performed and a small pouch of stomach at the extreme cardiac end was dissected from the diaphragm and the left lobe of the liver. Its capacity was probably not over 3 ounces. An antecolic and antiperistaltic gastrojejunostomy was performed without clamps. When the stomach was opened it was not possible to identify any outlet toward the pylorus, as this end of the stomach had contracted to the size of a No. 22 catheter entering through the previously made gastrostomy opening. An entero-enterostomy between the 2 loops of the jejunum was also established. Feeding was continued through the gastrostomy opening and in 2 weeks bougienage was again instituted. The patient was then discharged to the Eye and Ear Infirmary for repeated dilatations of the esophagus. The dilatations were quite painful but a No. 20 French bougie was passed at weekly intervals.

In July 1932 the patient was readmitted to the hospital for severe stomatitis. At this time the patient could swallow some milk but was depending for the most part upon the gastrostomy tube for feeding.

In September she was readmitted to the hospital still depending upon her gastrostomy feeding. Her general condition was much improved although the anemia had increased somewhat.

On September 29 esophagoscopy was performed by Dr. Campbell Smyth who reported a stricture 6 inches from the upper teeth that accommodated only a No. 15 filiform bougie.

On October 13 under local anesthesia the esophagus was exposed in the neck. It was found to be thickened and indurated. It was completely severed

Fig. 2 Patient with external (rubber) esophagus.

at a level of 2 inches below the upper border of the sternum and the lower end of the upper portion brought out to form an artificial stoma in the neck, as the first step toward the reconstruction of an external esophagus. This upper portion of the esophagus was then dilated by retrograde bougienage to accommodate a No. 32 French bougie. The patient was again discharged from the hospital returning on January 6 1933. At this time a laparotomy was performed and the loops of the gastrojejunostomy identified. One limb of the jejunum was severed just above the entero-enterostomy and its free end carried externally through a skin tunnel to a level above the nipple. The bowel sloughed to the level of the costal arch but at that point a good jejunal stoma was established. The cervical esophageal stoma was then connected to the jejunal stoma with a large, soft, rubber tube (Fig. 2) and by March, 1933 the patient was able to eat without difficulty a liberal solid diet. The gastrostomy tube was still kept in place. The patient refused further operative procedure at this point because of her satisfaction with the external rubber esophagus and she was discharged from the hospital with advice to return for observation and the construction of a skin tunnel esophagus.

Although attempts were made to keep track of the patient through the district nursing association no further co-operation was obtained from the patient or her family. Her alcoholic habits were resumed and she was ultimately taken to a local hospital in a semicomatose condition and died. At least she had the satisfaction of drinking herself to death.

Fig. 3. Cross section at level of fourth dorsal vertebra showing extrapleural route to mediastinum.

MEDIASTINITIS

Acute infection arising from perforation of the esophagus may follow the trauma of a foreign body or result directly from instrumentation. The characteristically virulent and fatal course is well known and in fact is one of the chief hazards of any procedure that involves the surgical manipulation of this organ. The division into two stages of the relatively simple operation for pharyngo-esophageal diverticulum is a surgical expedient designed to obviate infection.

Pearse has described a method for the immediate handling of perforations of the cervical esophagus that appears sound if the accident is recognized within a few hours. Frequently however perforation by an instrument is not recognized until mediastinal infection has already taken place, or indeed the peri-esophageal infection may find origin in an abrasion of the wall of the esophagus without actual perforation. If the infection remains localized, drainage through the esophagoscope may be adequate, but the diffuse mediastinal infections almost invariably prove fatal. In 2 such cases I have employed for the purpose of drainage a direct posterior approach to the mediastinum. As one patient

recovered it seems worth while to describe this procedure. It is quite possible that a cervical drainage route could have been established with an equal degree of success but in the absence of signs of infection in the neck I feel that the posterior approach directly to the mediastinum gives more effective drainage.

CASE 2. M.B. a school teacher aged 60 years, was subjected to esophagoscopy on February 18, 1932 for dysphagia. A spur was found on the anterior surface of the sixth and seventh cervical vertebrae pushing the esophageal wall forward and causing partial stenosis. Orthopedic treatment for her spine was carried out but the dysphagia persisted.

On June 11, 1932 another esophagoscopy was performed and during the course of the examination spontaneous emphysema developed extending upward from the neck to the eyes. The patient's temperature that evening was 103 degrees and she complained bitterly of pain in the chest. The following day she began to raise foul, thin, purulent material and although the emphysema was less marked her temperature remained elevated. In the period between June 14 and 20 the raising of foul, thin, purulent material continued and she was kept in the Trendelenburg position and given repeated injections of intravenous glucose.

On June 20 another esophagoscopy showed definite perforation of the wall of the esophagus with pus draining into it. The patient's general condition was still alarming with a high fever, rapid pulse and increasing weakness. X-ray examination

showed widening of the mediastinum and haziness of the lung fields. There was no tenderness or other sign of infection in the cervical region.

On June 29 under avertin anaesthesia an incision was made close to the spine over the upper portion of the chest and the lower portion of the trapezius and rhomboids were severed. The third, fourth, and fifth ribs were resected from the transverse process of the vertebrae to their angles and the transverse processes shortened. By blunt dissection the thickened and inflamed parietal pleura was separated from the lateral aspect of the vertebrae and the dissection carried forward until the lateral aspect of the posterior mediastinum was exposed (Fig. 3). An aspirating needle was inserted into the mediastinum and foul air with a small amount of pus obtained. Continued aspiration during the withdrawal of the needle yielded a free flow of blood showing that the needle had passed through the azygos vein into the mediastinum. About 2 centimeters cephalad to this point there was an area of the mediastinum that fluctuated with respiration (Fig. 4). An aspiration here immediately entered the mediastinum. A window approximately $1\frac{1}{2}$ centimeters in diameter was made at this point and foul necrotic slough with blood-stained pus obtained. The exploring finger entered between the oesophagus and the vertebral column. A very soft rubber tube was sutured to the walls of the opening into the mediastinum but was not inserted into the abscess cavity for fear of further erosion of the oesophagus. The incision was packed open with gauze. The patient ran a febrile course for 21 days then her temperature became normal and she was discharged from the hospital on the forty-fourth day. A small sinus persisted for some weeks but ultimately closed and the subsequent course of the convalescence has been uneventful.

CASE 3. E.C. an American woman aged 51 years, entered the Eye and Ear Infirmary on March 3, 1933 complaining of difficulty in swallowing of 2 weeks duration. Oesophagoscopy was performed and an annular obstruction found $1\frac{1}{2}$ inches from the upper teeth. A small amount of blood was encountered and no specimen was removed. Following the oesophagoscopy the patient complained of constant substernal pain. There was also marked pain on swallowing. Subcutaneous emphysema was observed in the soft tissues of the neck and upper mediastinum by X-ray. Her temperature ranged from 102 to 103 degrees with a rapidly increasing pulse and a discharge of foul pus by mouth. There was no sign of infection in the cervical region and as the patient's condition was rapidly becoming more desperate the operation described above was performed on March 17. Pus was encountered above the level of the azygos vein and an opening approximately 1 inch in diameter was made into the mediastinum. Thus foul pus and air were removed by suction and two large pieces of necrotic sloughing tissue picked out. The patient's condition rapidly became worse and she died 12 hours following the operation.

Fig. 4. Diagram showing site for entering mediastinum just above the arch of the azygos vein.

An autopsy revealed perforation of the oesophagus, phlegmonous oesophagitis with ulceration of the mucosa, gangrenous mediastinitis, bilateral bronchopneumonia and a carcinoma of the stomach.

CARDIOSPASM

Although the usual case of cardiospasm may be treated successfully by dilatation, need for more radical measures will be encountered from time to time. The development of surgical methods to meet these circumstances has been reviewed by Professor Bull of Oslo and by Mr. George Grey Turner (9), now of London, so my remarks will be limited to the reporting of 2 personal cases.

CASE 4. A.B., a housewife of 41 years was first examined in the Eye and Ear Infirmary on April 30, 1930. At that time she gave a history of cardiospasm dating back to a fall 11 years previously. At this time a therapeutic abortion was performed followed 11 months later by hysterectomy. A year after the hysterectomy the patient noticed her first difficulty in swallowing, associated frequently with convulsions. She described the food as almost reaching the stomach and then being held up and forming a distressing lump for which relief was found only in regurgitation or by its passing spontaneously into the stomach. She had been able to swallow only liquids and semisolids. Some solid food was 'washed' by the obstruction with the aid of water. She had at times vomited food that was 3 days old and had a foul odor. Three years before admission a period

Fig. 5. Incision for oesophagogastric anastomosis.

of complete inability to swallow food was relieved by a gastrostomy. This was utilized for a 6 months period and then allowed to close. Her weight during the 8 years previous to admission fell from 150 to 90 pounds.

At the Eye and Ear Infirmary a Mosher bag was passed twice with some improvement. Fluoroscopy showed dilatation of the oesophagus with retention of barium. She was treated by repeated dilatations over a period of 6 months. In June, 1931 she reported a further loss of 22 pounds. Later in August she reported that she was eating only liquid foods.

In October 1931 oesophagoscopy showed filling of the oesophagus just above the cardia but no evidence of ulceration or malignant disease. On November 16 1931 a gastrostomy was performed, the patient weighing only 91 pounds at this time. A high caloric vitamin-rich diet was given through the gastrostomy tube and she was discharged to continue this régime under the guidance of her own physician. She was readmitted to the hospital January 21, 1932 having gained over 7 pounds in the interval. Fluoroscopic examination showed a fluid level in the oesophagus at the level of the arch of the aorta. The barium meal revealed a dilated oesophagus with the usual tapering lower end and complete retention of the barium in the oesophagus.

On January 25 1932 following a crushing of the left phrenic nerve, an incision was made from the costophrenic angle to below the umbilicus. The gastrostomy incision was walled off by sterile drapings and not disturbed. Because of the narrow costal arch the ninth and tenth ribs were sectioned subperiosteally through a second incision in the mammary line. This gave an ample exposure al-

lowing mobilization of the left lobe of the liver (2). The oesophagus was freed from the hiatus of the diaphragm and pulled down until its dilated portion was exposed. It was then united to the stomach and a U-shaped incision was made with one limb extending to the dilated portion of the oesophagus and the other extending along the cardiac end of the stomach (Fig. 5). On opening the oesophagus there was no evidence of ulceration or peri-oesophageal inflammatory tissue but there seemed to be some thickening and fibrosis in the muscular layer of the oesophagus. The anastomosis was completed as in a Finney pyloroplasty and the line of suture enforced with omentum. Following the operation the patient was fed through a gastrostomy tube and her convalescence was uneventful.

On February 15, 1932 she enjoyed a meal of eggs poached and toast by mouth and was discharged from the hospital on a 6 meal bland diet.

In October 1933 she was eating everything by mouth except very heavy meats and doing all of her housework. The gastrostomy had been closed for some time. Fluoroscopy showed some delay at the cardia but a steady stream of barium entered the stomach. The patient had gained weight and was greatly pleased by the improvement following operation.

CASE 5. F. P., an American housewife aged 35 years, was seen in April, 1932 complaining of sub-sternal discomfort and epigastric pain of 8 months duration. There was no real dysphagia at the outset but regurgitation of liquids occurred when they were rapidly ingested. A month after the first symptoms, attacks of severe epigastric pain appeared, which were relieved by food or soda. These had increased in frequency and showed but slight improvement from dietary treatment. X-ray examination 3 months before admission showed a slightly dilated oesophagus with retention of barium.

Oesophagoscopy on May 5 1932 showed slight thickening in the wall of the oesophagus near the cardia. The mucous membrane was intact. There was no evidence of ulceration and a definite diagnosis was impossible, although carcinoma was seriously considered. The patient was placed on a 4 meal bland diet but continued to lose weight and suffered from regurgitation. Tincture of belladonna and nitroglycerin medication gave some relief but a second X-ray examination in September 1932 showed the same type of deformity in the oesophagus.

The patient was admitted to the hospital a second time in October 1932 the epigastric pain being less frequent but the regurgitation worse. She was kept on the wards for over a month, gained weight, but still complained of regurgitation and difficulty in swallowing. Treatment with the Hurst bougies was instituted while in the hospital and she was discharged under supervision to continue bougienage. Her general condition remained stationary but the continued pain which occurred particularly after passing the bougie led to its discontinuation because of the possibility of traumatizing an ulcer. X-ray

examination in October 1933, showed a constriction of the lower end of the oesophagus with marked retention and increasing dilatation.

The woman was again admitted to the hospital on October 19, 1933, and placed on a high caloric, high vitamin diet. She was able to take 8 ounces of liquid food every 2 hours so gastrostomy was not performed. Because of the severe pain accompanying the use of the bougie in this patient, it was decided to do a gastro-oesophageal cardioplasty.

On November 23, 1933 the phrenic nerve was crushed in the neck and the left lobe of the liver mobilized through a right rectus incision. The lower end of the oesophagus was mobilized to expose the beginning of the dilated area. No peri-oesophageal inflammation, oedema or scarring was disclosed. The lower end of the oesophagus was sutured to the stomach with silk and the opening into the mediastinum closed to prevent contamination. A U shaped incision was then made with one limb extending out of the cardiac end of the stomach and the other running up the oesophagus to the dilated area. Anastomosis was completed as in a Finney pyloroplasty and the left lobe of the liver re-suspended. Her ability to swallow improved immediately after the operation and although postoperative X rays showed the same dilatation of the oesophagus, the barium passed the cardia somewhat quicker. In her subsequent course the patient maintained the improvement although occasionally regurgitation occurs, particularly at times of mental strain.

Dr. Chester Jones who has followed the patient as medical consultant, considers her status 1 year after the operation to show 75 per cent improvement. Present X ray films show very little delay in the passage of barium from the oesophagus into the stomach.

We may conclude therefore, on the basis of these 2 cases and from the more extensive experience of others, that surgical measures find a definite even if limited, use in the direct treatment of cardiospasm.

SUMMARY

Illustrative cases from a limited experience in the surgery of the oesophagus are presented with comments.

The history of a case of impassable lye stricture is reviewed with special reference to the handling of the chemical injury to the stomach.

Posterior extrapleural drainage is advocated for mediastinal abscess following perforation of the oesophagus and a successful case noted.

Intractable cases of cardiospasm may be relieved by oesophagogastric anastomosis as illustrated by 2 case records.

FEBRUARY 15 1935

THE 1934 CLINICAL CONGRESS IN BOSTON

THAT American surgeons are seriously interested in improving their minds and exchanging with their colleagues knowledge they have found valuable in the management of surgical relief was evidenced to a superlative degree during our most recent clinical meeting. Through the combined efforts of the central and local committees on arrangements every possible clinical facility in greater Boston was made available to the visiting fellows. A wide variety of general and special work was demonstrated. Many extra features absorbed the unexpectedly large attendance in such an interesting manner that it is difficult to believe that any visitor failed to carry away some helpful suggestion. There was a spirit of willingness and co-operation demonstrated among the teachers in our medical schools and hospitals that would be hard to equal. That the meeting was a success is evidenced by the general feeling among the visiting Fellows and by the numerous expressions of their gratitude. Those who participated in the program were

enthusiastic regarding the high grade of intelligence the eager and attentive attitude of those who filled the amphitheatres in every hospital and in nearly every clinic or demonstration. Their feeling was one of general satisfaction that their efforts were appreciated.

The scientific sessions were attended to the capacity of the auditorium. Subjects of general interest were presented by authorities from this country and abroad in a manner that held these audiences until late in the evening. Conspicuous among these speakers were the younger full time professors of surgery from our American medical schools. Some of our distinguished foreign guests participated in these programs in a most charming and effective manner. New and important advances in surgery were presented and discussed without doubt carrying far reaching benefit throughout our nation.

Boston was honored by the central committee in that the outstanding researches of Prof. Harris P. Mosher of Harvard Medical School were recognized by an afternoon symposium on "Diseases of the Esophagus." Usually local authorities are not permitted to present their work at the scientific sessions.

In addition to the operative and dry clinics in the larger hospitals of Boston which are always crowded the splendid suburban hospitals were well attended. To these more distant clinics transportation was provided by the hospital, and if the session occupied the entire day luncheon was served. That these efforts were of great value and appreciated, there can be no doubt.

The special hospital conferences were of interest as usual, and the attendance was

large. Other special conferences, on cancer, fractures, industrial medicine and traumatic surgery, were well attended. These special features of the work of the College are obviously of such importance that a continuation of such activities is necessary.

The clinics of the eye, ear, nose and throat sections were all overcrowded. Their scientific sessions were held in a special auditorium admirably suited to their needs. Many distinguished guests participated in their program all to the advantage of those Fellows interested in these specialties.

The community health meeting on Wednesday evening at the Arena was a revelation to greater Boston. There was considerable doubt in the minds of the local committee whether this great auditorium would be filled. The program was of such character however, as to attract a capacity audience. More than 10,000 of our citizens were sufficiently interested in their health to attend. Actually some 2,000 who sought admission were unable to find seats. That this will be of widespread benefit in our community is certain. Enthusiastic reports continue to come in.

The motion picture exhibitions were excellent. Many new films of approved surgical procedures were included this year. One found a continuous stream of visiting Fellows slipping in and out of this projection room. This graphic method of teaching standard methods for specific problems in surgery is of utmost value.

An attempt was made to display a limited number of scientific exhibits. These were mainly by local contributors. The only space

available was the gallery of the Statler Hotel ballroom. In spite of the inaccessibility of this arrangement it was found that many were interested and spent much time in this department.

A new feature sponsored by Dr. Shields Warren was the demonstration of fresh pathological specimens from the operative clinics each day. These were brought together and discussed by our eminent pathologists. The specimens were shown on the screen by means of the Zeiss episcope, and were of natural color and without distortion. It was possible for one to see in this manner the specimen he had seen removed that morning in the operative clinics.

At the Boston Medical Library much interest was exhibited in the historical pageant sponsored by Dr. Spector and given by the students of Tufts Medical School. Dr. F. B. Lund gave a charming and interesting illustrated lecture on the surgery of ancient Greece. Here also were exhibited the artistic hobbies of the Boston profession. Many of the Fellows enjoyed this pleasing feature.

The Presidential Meeting on Monday evening and the Convocation on Friday evening at Symphony Hall were impressive as usual. The addresses of Dr. Haggard and Dr. Greenough, the Murphy Oration by Dr. Balfour and the Fellowship Address by Dr. Lotus D. Coffman were all thoroughly enjoyed. The high grade of the candidates accepted was gratifying. It is felt that Boston may be proud to have acted as host during a Clinical Congress so obviously successful.

ARTHUR W. ALLEN

PRESIDENTIAL MEETING, CONVOCATION

ADDRESS OF WELCOME¹

ARTHUR W. ALLEN M.D. F.A.C.S. BOSTON, MASSACHUSETTS

ON behalf of the local Committee on Arrangements, it is my pleasant privilege to bid you welcome. It is particularly fitting that this Twenty fourth Annual Meeting should be held here as your President-elect Dr. Robert B. Greenough, so admirably typifies Boston surgery. His untiring efforts in the advancement of education and service to humanity, make it assured that your institution will thrive under his leadership. Boston has always stood for a high standard of education. This has been true in medicine and surgery and community service. Our predecessors have made great contributions to science. Among them are the Warrens, Oliver, Wendell Holmes, Bigelow, Cabot, Richardson, Fitz Minter, Homans, Cheever and the Porters. Some of these have left sons, but all have left disciples to carry on the torch of learning, teaching, and service to mankind.

It has been six years since the Clinical Congress of the American College of Surgeons visited our city. During this interval there has been a considerable increase in our clinical facilities. New hospital buildings have been erected and modern equipment installed. The standard of service has kept pace with these improvements. It seems fitting to mention particularly the excellent hospitals and high grade of work now found in our

suburban communities. We wish it were possible for each of you to visit these splendid clinics and many of you will have this opportunity.

The medical schools and hospitals of greater Boston have seriously attempted to utilize every available facility to make your stay with us worth while. We realize that all of you will not be able to gain admission to each feature of the program that you may select. Let us urge you to accept with good grace some alternative clinic or demonstration for an effort has been made by the combined local and central committees to offer you nothing that will fail to be of interest. At the medical library there will be an opportunity to see interesting features pertaining to the history of our science. Also here will be displayed works of art as an illustration of a pleasing hobby by members of our local profession. Numerous other entertaining and instructive possibilities have been made available.

To those of you who are honoring us by your first visit, let us remind you of the many points of historic interest in and about this old City of Boston. You may become lost in the maze of our crooked streets but you will find our citizens courteous and helpful. It is our earnest desire that your stay with us be pleasant, interesting and beneficial.

Presented before the Clinical Congress of the American College of Surgeons, Boston, October 7-10, 1934.

THE BACKGROUND OF THE AMERICAN SURGEON¹

WILLIAM D HAGGARD M.D. F.A.C.S. D.C.L., NASHVILLE, TENNESSEE

In their life and doctrine, they (our forbears) set forth a true and lively word to the great enlightenment of our darkness — OSLEK.

SURGERY has a noble heritage. Its disciples are the intellectual descendants of all the great minds who have glorified time. There has been an apostolic succession in surgery from the Father of Medicine to each Bishop in our Priesthood to the latest devotee who enters the sacred portals. Galen, Avicenna, de Chauhac, Paré, Harvey and Wiseman who was a bridge of one plank from the seventeenth century to Cheselden, down to the immortal Lister who gave 'a new Heaven to medicine and a new Earth to surgery.' His carbolic dressings due to Pasteur were more potent than the sweet smelling spices that Rebecca poured upon the wounds of Ivanhoe.

The background and tradition of the surgeons of the New World are predominantly British. Before the arrogant George III lost the American colonies, the best medical men in the new country were graduates of the University of Edinburgh.

Scotland's darling seat. There surgery was in full bloom. Munro I, II, and III and their colleagues flourished. The Bells were great ornaments. In London there were Parry, Cullen, Abernethy, the five custodians of the Gold Headed Cane, and the immortal Jenner, friend of John Hunter and godfather to his son. When 'the Great Surgeon' was spoken of in the days of Macaulay, the people thought of Brodie, as when they said 'the Duke it meant Wellington. There were also in that great constellation, Colles, Fergusson, Erichsen, to whom Lister was house surgeon, Simpson, and Paget. Some of these reached the empyrean, and to use Shelley's words, 'robed in dazzling immortality, sit on thrones.'

John Hunter, next to Hippocrates in the opinion of Gross, was the greatest figure in the history of medicine and the most remarkable observer of nature since Aristotle. Hunter, that lordly soul, raised surgery from the cruder and simpler procedures to the dignity and responsibility of a true science. He created a unity between physiology and pathology and linked them with the natural sciences. A brilliant number of ambitious American medical students brought back Hunter's methods and those of the great contemporary teachers and from them has developed the flowering splendor of the surgery of America, that country apostrophized by Tennyson as the—

Gigantic daughter of the West,
We drink to thee across the flood.
For art not thou of English blood?

American civil polity and supremacy among the powers is the marvel of mankind. What is denominated Americanism is the same spirit which finally subdued imperial Rome after 500 years, which stopped the hordes at Poitiers rolled back the tide of Asiatic invasion beyond the Pyrenees, and preserved civilization from oriental degradation. Americanism incarnate gave the idealism for right against might in the World War and preserved by blood and treasure the allied nations.

In the earlier days our civilization 'was nursed by strong men with empires in their brains.' The first American surgeon of whom we hear was the sterling John Jones, who with Hunter studied under Percival Pott fought in the Colonial and French wars was the first teacher of surgery in King's College in 1767 and the first in America to perform lithotomy.

William Shippen Jr. of Philadelphia, physician-general to Washington's armies, special pupil of William Hunter, was professor of surgery in the University of Pennsylvania which he helped found in 1765. Shippen with Jones of New York and Warren of Boston—the triumvirate of early pioneer surgeons living in the three large cities—disseminated their teachings throughout the 13 states.

The fertile soil of America has produced patriots, poets, scholars, and inventors but none has contributed more for human weal and happiness than the surgeon. In the first quarter of the eighteenth century, a writer in the *Edinburgh Review* asked "What does the world yet owe to American physicians and surgeons? Suppose that question were asked now. What would history answer?"

A brief epitome of the historical drama of American surgical achievements, like a trans-continental airplane looks upon the high peaks only among many great mountains. Peer reverently with me unto some of the treasures of biography.

The Warren dynasty of 5 generations gave to Boston historic and epochal events in the march of American surgery. John Warren founded the Harvard Medical School in 1782.

He built beyond mortal thought—
Far in the Unapparent.

¹Address of the Retiring President, presented before the Clinical Congress of the American College of Surgeons, Boston, October 28-30, 1934.

When the Charlestown ferry to Cambridge was stopped by ice he went round by Roxbury performed his own dissections and lectured 3 hours. While Napoleon was divorcing Josephine, the Harvard Medical School was divorced from Cambridge. John Warren's older brother Dr Joseph Warren, was killed at Bunker Hill. Warren later crowned that acropolis with sublimity at the time Monroe was enunciating his doctrine.

John Collins Warren studied with Sir Astley Cooper. Cooper was trained by Henry Cline, who tapped the enormous hydrocele of Gibbon and withdrew 6 quarts of fluid. Warren was a dresser at Guy's Hospital for which privilege he paid two hundred and fifty dollars a year. John Keats was also a pupil at Guy's with American students in 1817. He abandoned medicine and in a year his imperishable "Endymion" shot through the heavens like a meteor. After graduating at Edinburgh, Warren lived in Paris with Napoleon's surgeon, Du Bois. He, with James Jackson, established the great Massachusetts General Hospital 113 years ago. There was destined to be enacted the great drama of anesthesia "the death of pain." It was joyfull news out of the new found world. The eighty-eighth anniversary of Ether Day will be celebrated tomorrow because a Warren dared to employ ether while William T. G. Morton hopefully administered it. Warren risked his unrivaled reputation, to say nothing of the life of his patient in this most sublime experiment. He was a great teacher—the surgical autocrat of New England—and dominated the Hunterian era. The first operation in America for strangulated hernia, Warren did. He introduced asthylotherapy. He did amputations and cataract operations with great celerity. Longfellow his patient, said that he had the eye of an eagle and a woman's hand.

Ether anesthesia, however, was first intentionally produced for the abolition of pain in a surgical operation by Crawford W. Long, of Jefferson, Georgia. "a spot in the wilderness of a new continent," in 1845. Long used ether in childbirth delivered his wife under ether and performed one or more operations under its influence annually thereafter. Unfortunately he did not publish his work until 1849.

Philip Syng Physick has been called the Father of American surgery and had a chair of surgery apart from anatomy created for him in the University of Pennsylvania, in 1805. Through the influence of Hunter he received his house-surgeryancy at St. George's hospital. "Physick was almost as much a mouthpiece of the doctrines of

John Hunter in America as was Abernethy in London. Both had many disciples but neither left a great successor. Physick paced the alleyways of Philadelphia for several years before he earned enough to powder his cue. Stephen Girard was his intimate friend and Benjamin Rush his closest associate. Physick was the first to do lateral anastomosis by compression of the two loops of the intestine by artificial anus following strangulated hernia the principle in Mikulicz's operation as done today. He also removed a thousand calculi from the bladder of Chief Justice John Marshall. He invented the tonsillotome. He wrote not at all. His students were his publishers. Physick first employed the absorbable ligature. He was the first to use the stomach pump for poison, the first to operate for imperforate anus. Physick lived in terror lest his body be dissected, whereas John Warren made a legacy in his will that his body should be dissected and his skeleton hung in the lecture room. Gross believed that Physick raised American surgery from its somewhat low state and so developed it that it soon became equal to the best surgery of Europe. Physick ignored the report of the first ovariectomy by the lion-hearted McDowell in 1809 but he was not ignored by the Goddess who emblazoned his name on the Roster of Immortals.

Nathan Smith a frontiersman in surgery performed an ovariectomy in Vermont in 1821 without the knowledge of McDowell's operation. He removed a 10 pound tumor and dropped the pedicle after tying it with a leather ligature. He founded Dartmouth Medical School in 1808, established the medical department of Yale College, New Haven, and filled the chair of surgery in 1813. Welch said of him that he did more for the general advancement of medical and surgical practice than any of his predecessors or contemporaries in this country.

"Premier surgeon of the West," Benjamin W. Dudley of Lexington Kentucky after graduation at the University of Pennsylvania, studied abroad. The money for his European education was obtained by taking a flat boat of produce to New Orleans, exchanging it for flour transporting it to Lisbon, where he sold it for enough for a 4 years course in London and Paris. He did 225 lithotomies with 222 recoveries. He was the first to ligate the subclavian artery for an aneurism, (larger than a quart pitcher), in 1825. His success was largely due to the use of boiled water and the boiling of his instruments. In 1818 he challenged Daniel Drake the great man of the West, to a duel which was declined, and his friend, Dr Richardson who took it up was shot in the groin

but saved by the skill of Dudley who quickly ligated the femoral artery. He and Drake became fast friends and colleagues in Transylvania University, the first medical school west of the Alleghenies. Drake inaugurated most good and great things in Cincinnati, but that did not prevent Dudley from essaying to make a rent in the robe of *Æsculapius*.

Valentine Mott, also a pupil of Astley Cooper, was the most famous of the New York surgeons. His contemporaries even regarded him as heroic. In 1813, he excised the clavicle completely for osteosarcoma. It was the day before Waterloo when her beauty and her chivalry had gathered in Belgian's capital. Mott tied the primitive carotid 51 times and the femoral 57 times. The first ligation of the innominate artery he did in 1818. In 1826, he reported the first successful ligation of the common iliac artery. In all he performed 138 ligations. He lectured for 36 years continuously.

George McClellan founded Jefferson Medical College in 1825 and invented teaching by public clinics. He wore a swallow tail coat and made his daily visits in a chaise. It was the year when Lafayette made his last triumphal tour to the United States. The son of George McClellan commanded mighty armies and stood upon the flaming brow of Malvern Hill. Brilliant, bold confident operator he was the first to excise the parotid gland.

J. Marion Sims, a South Carolinian, born near the native heath of Andrew Jackson, did his memorable work in the cure of vesicovaginal fistula at Montgomery, Alabama, and made lacerated women whole. What prodigious effort, what abounding faith! He had operated upon the slave, Anarcha, twenty nine times with twenty nine partial or complete failures when, on that May day in 1849, he used the silver wire suture for the first time. It was an entire and complete success. Sims established The Woman's Hospital in the state of New York in 1855 which was the fountainhead of gynecology. He was succeeded by T. Addis Emmet, master gynecologist. Sims demonstrated his operation before Nélaton, Denonvillier, and Velpeau. While living in Paris, he attended the Empress Eugénie at St. Cloud and was physician to the Duchesse of Hamilton. He operated in many of the capitals of Europe. A heroic statue of Sims stands facing the New York Academy of Medicine.

The lure of the Napoleonic era took many American students to Paris. In the second third of the nineteenth century, it had supplanted Edinburgh as the popular mecca. The French

took the torch. Laennec and Trousseau occupied the teaching forum and had the world as an audience. France was the crucible of civilization. Science, art, and surgery vied with literature, drama, and vice.

Henry I. Bowditch studied under the great Louis. While Trousseau had suggested thoracostomy, Wyman designed and employed the trocar and cannula and the technique in 1850 with Bowditch, who is said to have aspirated the chest after that some three hundred times without a fatality. The celebrated Dupuytren died of empyema rather than submit to aspiration, saying that he had never known anything to succeed.

Henry J. Bigelow was one of the most brilliant of the products of the French school. A revered teacher, beginning in 1849 in Harvard, he discovered the iliofemoral (Y) ligament of the hip joint. His greatest contribution was in lithotomy by the perfection of the lithotrite. Stones crushed and removed by the evacuator at one sitting was a procedure perfected by him in 1878.

Samuel D. Gross was the most conspicuous surgeon of his day between the era of the French and German ascendancy. He was denominated 'the master of American surgery', born in 1805 the year of Austerlitz and Trafalgar. Gross was an office student of George McClellan. He excised the trifacial nerve, invented the urethrotome, and perfected the treatment of stab wounds. His monumental treatise on surgery was begun while he was professor in Louisville. It was the first great American authority. When he spoke, 50 years of American surgery was speaking through his lips and he has been referred to superlatively as having earned the royal title of the emperor of American surgery.

The remarkable times in which the pioneers lived emboldened them to perform operations that had never been done before. Abdominal section of the extra uterine pregnancy was done by a bold surgeon in New York, John Bard, in 1759. It was not until 1804 that Lawson Tate did the first operation of the sort in England. William Baynham, of Virginia, performed the operation for extra uterine pregnancy twice with success in 1799 in Essex County.

Dr. Jesse Bennett, in Virginia, did a cesarean section on his own wife in 1794. Cogswell was the first to ligate the primitive carotid successfully for primary hæmorrhage, in 1803. Walter Brashear of Bardonia, Kentucky, did the first successful amputation of the hip joint, in 1806. Deaderick of Tennessee removed a large part of the lower jaw, in 1810. Francis Fontaine Maury, a native of Kentucky, performed the first operation of gas-

trotomy in this country. Kinloch, a Charlestonian, General Lee's staff surgeon, was the first to open the abdomen in case of gunshot wounds where there was no protrusion and sutured the perforations. William T. Bull has the distinction of first successfully opening the abdomen and suturing the perforations of a gunshot wound in 1885.

The first nephrectomy appears to have been performed by Winkott in Milwaukee in 1861. 8 years before Simon performed the first case in Germany.

Dr. John S. Bobbs, of Indianapolis, did the first operation on the gall bladder from which a number of gall stones were removed. The patient recovered and was taken to the Portland meeting of the American Medical Association in 1902 where some of you may have seen her as did the speaker. The first splenectomy was done by Dorney in Piqua, Ohio, in about 1855.

The first hysterectomy for a fibroid tumor of the uterus was performed by Walter Burnham of Lowell, in 1853.

Hunter McGuire, one of the most distinguished teachers of surgeons in the South, was Stonewall Jackson's surgeon. He was the first to tie the aorta after Sir Astley Cooper (1868).

New Orleans furnished a brilliant group. To Warren Stone is ascribed the first resection of the rib for drainage in empyema and abscess of the liver. T. G. Richardson was the first surgeon to do a bilateral amputation of the hip joint at the same sitting in 1843.

Smith was the first to cure an aneurism by ligation of the innominate artery in 1864. Mott's first case in 1818 was unsuccessful. Miles and Parham flourished and were succeeded by the surgical scholar and seer of America, the full-orbed star of the Crescent City.

Louisville produced Vandell, the scholar, and Matthews, the courtly surgeon. McMurtry was the chevalier and apostle of the new abdominal surgery.

Nashville was graced by Eve, surgeon in four wars, who taught surgery to 454 students in 1859, the largest medical class ever gathered together outside of Philadelphia, and Briggs, also a lithotomist, both presidents of the American Medical Association. Haggard, who with W. E. B. Davis of Birmingham founded the Southern Surgical Association in 1888, and the brilliant Douglas.

In California Henry Gibbons gave the first course of medical lectures on the Pacific Coast in 1850, and his first patient was said to have dropped an ounce of gold dust on his desk (value of \$16) as his fee. The other great pioneer sur-

geons of San Francisco were Gibbons, Cooper Toland Lane and Goodfellow, who was the exponent of the earliest prostatectomy.

The Northwest found the elder Mayo laying the foundation of the greatest surgical development yet witnessed not only in America but in the entire surgical world.

About 1860 the begira to Germany by American students began. Virchow, Traube, and Langenbeck were the tripod upon which pathology, medicine, and surgery rested. Langenbeck was the most dexterous surgeon of his day. It was said that a man who came to see him do an amputation, paused to take a pinch of snuff and when he had sneezed the operation was over. Efficiency and great devotion were inspired by the masters—Kocher, Trendelenburg, von Bergmann, Billroth and Mikulicz.

Keen was the first to bring back antisepsis to Philadelphia after his German tutelage. With his friend, the gifted S. Weir Mitchell, he made studies abroad on gunshot wounds and nerve suture. He was one of the first teachers of pathological anatomy. His pen was as mighty as his scalpel. He was the Nestor of surgery in our time. Joseph Pancoast, to whom was referred the daughter of the Lord Chancellor of England by Sir William Ferguson as the greatest plastic surgeon in the world, antedated him. We see also in Philadelphia the flashing scalpel of Agnew, whose clinic is immortalized in one of the strongest paintings of modern times.

In Canada, surgery had an almost exclusive English background and produced such stalwarts as Shepherd, Armstrong, Starr, and the great universalists at Montreal and Toronto.

In New York in the latter half of the nineteenth century were Van Buren, Buck, James R. Wood, Frank Hamilton, T. Gaillard Thomas, Sand, preceded by Willard Parker, who did much to familiarize the profession in 1861 with the wisdom of operating for appendiceal abscess. The metropolis has had in the last four decades a long list of surgeons of stellar brilliance—of these McCosh, Abbe, Gerster, Wyeth, Bryant, Dennis, Stimson, Weir Bull, and Peck have luster.

Charles McBurney and Reginald Fitz did their transcendent work in appendicitis. McBurney perfecting its operative treatment in 1889, after Fitz described its pathology a year before. They both passed into the Valhalla of surgeons in the same year—1913.

Philadelphia, the cradle of surgery, had, as its pride, the Ashursts, White, Rodman, the matchless Deaver, and Da Costa—scholar, author, teacher—who said, "No one knows of the ham-

ing anxiety, the deep disappointments, the baffling perplexities, the dread responsibilities, and the numerous self reproaches of one who spends his life as an operating surgeon. His hand must be as light as a floating perfume, his eyes quick as a flashing sunbeam, his heart as broad as humanity, his soul as sweet as the waters of Lebanon."

Baltimore was first seen in the firmament by the light of William Gibson who was a pupil of Sir Charles Bell and a friend of Byron, and who was wounded at Waterloo. He was the first to perform the operation of ligating the common iliac artery in the year of our last war with England. Baltimore's fame was enriched by William S. Halsted, founder of the Hopkins School of Surgery who did great work in conduction anesthesia, carcinoma of the breast, goiter, hernia, and many other fields touched by his genius, which is never to be forgotten. This luminous figure having no children of his own, was the prolific Father of Surgeons.

Among Boston's great are remembered Cheever, Homans, Cabot, the Porters, Mixer Munro and the great hearted Maurice Richardson who taught the newer abdominal surgery, and, as Mumford said of Oliver Wendell Holmes, sat for years amid the Esculapians in the seat of honor.

In Cincinnati there was Connor Dandridge and Ransohoff, in the twin cities Wheaton, Moore, and McLaren. When we think of Albany we think of Van der Veer, of Buffalo of Roswell Park, of San Francisco, Harry Sherman and Tom Huntington, of Richmond George Ben Johnson, of St. Louis, McDowell, Pope, Hodgen—who devised the ingenious and useful suspension splint of Texas, Thompson, and of the Pacific North west, the late lamented Coffey, who devised safe ureteral transplantation.

The radiant sun of modern surgery that was to shine so effulgently over Chicago had its dawning with the arrival of Daniel Brainard in shabby clothes on an Indian pony. He found not more than one hundred people around Fort Dearborn. In 1837, he took out a charter for the Rush Medical College and after a season of study in Europe opened the College in 1843. Brainard's work was original on ununited fracture, the invention of the bone drill, and iodine injection for spina bifida.

Moses Gunn, a luminary was succeeded by Charles T. Parks, physically and mentally a gem. Edmund Andrews was the first to employ nitrous oxide in general surgery. The group that made Chicago famous as the clinical center of the West comprised Fenger, Senn, Murphy, and Ochsner.

Fenger brought the new pathology to America. Senn waited table for his board while practicing in Milwaukee and made the experiments in intestinal anastomosis in his basement, but at the International Congress in Moscow he was acclaimed the Premier Surgeon of the World when he presented his paper on "Pentonitis" and was carried on the shoulders of his ardent admirers.

Murphy—greatest of American surgical teachers—cured ankylosis, introduced therapeutic compression of the lungs and invented the most exquisite surgical device in the world—the Murphy button.

Ochsner, chief of staff of Parks and Senn, became one of the greatest surgeons in our time and had the largest individual private surgical clinic in America. His voluminous writings covered many subjects and covered them well.

These are some of the great surgeons of the Western World. Many wore the splendid robes of fame many 'the muses decked with gifts of grace.

This rich background is your precious professional heritage. Hold it to your heart and cherish it.

Not Mars his sword nor war's quick fire shall burn
The living record of their memory

The pride we have is not chauvinistic. We hail the improvements of our art from any clime. Far from being self satisfied in the plenitude of our science it is the principle of our guild to acclaim any real contribution to science whatever its country in the effort to prevent disease and mitigate its blight. Surgery has made such vast conquests that we cease to wonder. Its beneficent factions make the angels rejoice.

Shall we be content?

Descartes said that if there is any possible way of increasing the wisdom and ability of mankind it must be sought in medicine.

What shall be said for that great multitude of American surgeons who did not teach or write?

What of those who never sing,
But die with all their music in them?

They have lived to lessen the sorrows and assuage the anguish of mankind for the surgeon is a gleam of sunshine in the patient's dungeon when the loved ones are wrapped in black despair.

What a rich inheritance to be a surgeon in America my America!

In the land of youth and freedom beyond the ocean bars
Where the air is full of sunshine, and the flag is full of stars.

EFFICIENT SURGICAL SERVICE FOR THE WHOLE COMMUNITY¹

ROBERT B. GREENOUGH, M.D., F.A.C.S., BOSTON, MASSACHUSETTS

UNDER the broad charter of its articles of incorporation, the American College of Surgeons has brought about outstanding improvements in the practice of surgery in this country in the 22 years of its existence. It has set up qualifications for Fellowship of such a nature that the public may have confidence that every Fellow of the College is in fact worthy and competent to practice his designated branch of the art of surgery. The results accomplished by the College in its standardization of hospitals are world-renowned and the work of its committees on fractures, cancer, sarcoma, and traumatic surgery has contributed greatly to the improvement of the quality of surgical service supplied to the community.

Within the past few years, however, it has become increasingly apparent that competent medical and surgical service is not everywhere to be obtained by all classes of the population.

Depression and unemployment have been responsible for the more general appreciation of these facts, and have indeed been to a considerable extent the cause of them, but few will deny that the provision for efficient medical and surgical service including preventive medicine, has not for some time past been sufficient to meet the needs of all classes of the community. As Fellows of the American College of Surgeons, these facts deserve our serious consideration.

In the 20 years which have elapsed since the beginning of the great war profound changes have been taking place throughout the world, which have so altered the habits and thoughts of people of all nationalities as to produce almost a new civilization. During this period the advances of science have been unprecedented, and the application of these advances to the daily life of the people, whether in the form of new inventions to enhance their comfort and happiness or as additions to the resources of medical and surgical science for the protection of their health, has contributed greatly to the welfare of mankind. This has been a period of mechanical and technological ascendancy and of quantity production. In the widespread development of new methods of production and distribution of the essentials of existence, it is not surprising that the older methods of supplying medical and surgical service should have been criticized as ineffective. As a matter of fact, medical practice has not remained alto-

gether immune to these new influences, and the development of specialization in medicine and surgery is an example of the modifications which the scientific advances of this period have made necessary as the sum of medical knowledge has increased. It is as a result of these developments that the group method of practice has come into existence.

As a rule, however, the medical profession has resisted attempts to extend mass production principles to the practice of medicine. It is their belief that the peculiarly personal and fiduciary nature of the relation between patient and physician is too precious a relationship and one of too much value to the community to be jeopardized by radical changes of a socialistic nature. This attitude on the part of the profession is one to be commended rather than condemned. The individual member of the community is dependent upon his medical advisor for the maintenance of his health and functional efficiency. In the opportunity to select the physician or the hospital in which he has confidence rests the first step in that relationship of trust which plays so great a part in the satisfactory conduct of medical practice. The physician has been trained to accept the grave responsibilities that are involved in this fiduciary relationship and the Hippocratic oath is evidence sufficient that this important feature of medical practice has been recognized both by the public and by the profession since before the Christian era. This peculiar responsibility of the physician is further safeguarded by the code of ethics which is universally accepted by the medical profession. This code of ethics is designed primarily to protect the patient and the community by the elimination of those physicians who are unworthy or unwilling to accept the altruistic principles upon which the satisfactory conduct of the practice of medicine must inevitably rest.

Living conditions in this country however have been profoundly altered in the past 5 years. Depression and unemployment have reduced many individuals from a position of relative independence to one of indigence, and have brought those who were once in easier circumstances down in the scale of living below the comfort level. At the same time the reduction of the incomes of the well-to-do has been such that sums they formerly contributed to charitable purposes

¹Invited Address, presented before the Clinical Congress of the American College of Surgeons, Boston, October 2-4, 1934.

have been greatly reduced in amount, and in some cases have been abandoned altogether.

Under these circumstances, it is not surprising that town, county state, and finally even federal authorities have been obliged to assume increased obligations in order to provide even food and lodging for the destitute. The resources of the towns and counties have proved in many localities to be insufficient and the former scanty provisions for the medical care of the indigent have become even less adequate than they were before. The extra burden has fallen chiefly upon the physicians and surgeons of the community to supply medical and surgical service to the indigent sick without remuneration. To this call of humanity physicians have responded, as one of the duties and obligations of a great and honorable profession. As a result, however, many members of the medical profession have by this time themselves been brought perilously near to the level of indigence. More effective methods of supplying medical and surgical service to the community, and especially to the indigent and to the lower income groups of the population, and of providing suitable remuneration for those who give this service is an immediate and urgent necessity. Not only is this necessary to maintain the health of the community itself but it is needed also to preserve the medical man-power of the country. The amount of time and money involved in the education and training of the physicians and surgeons of the United States represents an enormous investment of time of money and of effort and one which if destroyed could not possibly be replaced for a period of many years. What has been said in regard to the medical and surgical personnel applies with equal cogency to members of the dental profession to nurses, social workers, laboratory technicians and all of the ancillary professional groups who are concerned in supplying medical and surgical service to the population.

While the present situation is of grave importance to all of the professional groups that gain their livelihood by participation in the provision of medical and surgical service it is of special concern to the surgeons of this country. The injuries and diseases the surgeon is called upon to treat almost invariably require hospitalization and a more or less extended period of subsequent supervision. All too frequently these hospital expenses exhaust or exceed the patient's limited resources and further payment for professional service becomes impossible.

We recognize that hospitals are doing their utmost to cut their cost of operation to the lowest

possible figure. Ingenious projects for greater economy have already been instituted in hospitals all over the country. Conferences of the hospital department of the College have been devoted to this subject, and these efforts on the part of the management should be heartily supported and to a great extent guided by the members of the hospital staff. The chief and final consideration which must be recognized in this respect is the quality of service which the hospital can supply. Economies which lower the quality of this service must be avoided or the safety of the community will be seriously impaired.

From the point of view of the surgeon the quality of service given to the community is of supreme importance. Very few of the injuries or diseases with which the surgeon deals are of the self limited class or tend of themselves to spontaneous recovery. The patient who requires surgical treatment is generally one in whom some gross mechanical condition is present, which must be removed or corrected before that individual can be restored to health. A great part of the surgeon's work is also necessarily of an emergency character and deals with injuries and acute diseases and with the acute and imperative complications of more chronic disease. In all of these conditions delay is dangerous, and what is of equal and sometimes greater importance, the moment for efficient treatment is fleeting and what must be done, must be done not only promptly but correctly, or the patient's chance for recovery may be irretrievably sacrificed.

The first and most important element in the delivery of efficient surgical service then is the qualification of the surgeon for the work he has to do. With the varying state laws for licensure to practice the healing art, we are at once confronted with the fact that the qualifications of the physicians and surgeons admitted to practice in the different states are by no means uniform. Furthermore, there is only one license in a given state, and this permits the physician or surgeon to practice any form of medicine or surgery for which he may consider himself qualified. His conscience, indeed, is his only guide. This is true even of the licentiates of the National Board of Medical Examiners who are admitted to practice in a number of different states without further examination.

Every graduate of a recognized medical school and every physician who holds a license to practice medicine in the different states of the Union has been taught the general principles of surgery. In general practice and especially in districts remote from the great centers of population, the

physician must be prepared to give surgical as well as medical service, especially in emergencies, for he is frequently the only possible source of aid at such a time. The American College of Surgeons now carries eleven thousand surgeons on its rolls as Fellows of the College, but it would be manifestly impossible for all the surgical service needed by the community to be given by these qualified surgeons alone. For emergency service and for minor surgical procedures the community must not infrequently be dependent upon the general practitioner. Let it be said at once that the efficiency with which such service is supplied, day in, day out, all over the country by physicians in general practice is deserving of the highest praise and the widest recognition.

For major surgical service however prolonged training, more intense application to this restricted field, adequate laboratory and hospital equipment, and the judgment and dexterity obtained only from experience, are qualifications which the physician in general practice cannot readily obtain. The more specialized surgical service of the community must therefore be provided by those who have established their ability and fitness to give this service, and these qualifications Fellowship in the American College of Surgeons is designed to certify.

When we reflect, however, that in spite of the lack of any legal restraint, the medical profession has been so effectively controlled by its principles of ethics as to prevent the abuse of public confidence by the individual practitioner attempting to do surgical work beyond his capabilities, we must acknowledge again a high degree of moral sense and altruism as having been established as a tradition of the medical profession.

The American College of Surgeons represents the only existing organization designed to establish definite and distinct qualifications for the practice of surgery. Similar organizations exist for the qualification of specialists in some of the other branches of medicine but the field is by no means covered by these independent agencies.

The amalgamation of all of the different boards for the certification of specialists under some co-ordinating influence is at present under consideration and would undoubtedly lead to a more satisfactory appreciation by the public as well as by the medical profession, of the value of such qualification. It would be unreasonable and unwise, however, for the individual State Boards of Registration to attempt each to set up its own standards for the licensing of physicians and surgeons in the different specialties. Certification of specialists should be national in scope, reasonably

uniform in its requirements, with due regard to the varying demands of each form of special service and above all things, should demand a broad general medical and surgical training as a foundation upon which specialization may be firmly based.

Since no single national organization exists at the present moment for the certification of physicians and surgeons as to their qualifications for practice of all of the different special lines of medical activity we must seek some other means of classification if we desire to deliver the most effective service to the community. Such a means is available to us in the hospitals. All but the smallest hospitals maintain such a division of their staffs, varying from the primary separation into surgical, medical and obstetrical divisions up to the divisions of the larger hospitals into separate services and clinics in 15 or 20 different specialties of medical and surgical practice. Physicians and surgeons in hospitals are further classified into permanent staffs and courtesy or associate staffs, but no hospital worthy of the name fails to exercise control and supervision over the work of its staff to give serious consideration to the qualifications of candidates for its staff appointments, or to withhold appointment from those who are not professionally qualified or are otherwise unworthy.

The classification of specialists which is provided by the hospitals, may well be utilized in any plans for providing more efficient service to the community. Since the hospitals themselves are an essential part of any such project, they may prove to be the most satisfactory units with which to construct these plans, and in any case their co-operation and participation will always be an absolute necessity.

It is not necessary however that such plans should be restricted to hospitals which have been approved by the American College of Surgeons. The advantages of such approval are today so obvious to the trustees, staffs, and patients of every institution, and to the public as well, that no small part of the benefit which has accrued to the community from the hospital standardization movement is the notable improvement of conditions in all hospitals, including particularly those which have not yet succeeded in reaching the minimum standard of the College but which are steadfastly approaching that goal of their ambition.

From early colonial times up to the present day it has been an accepted principle in this country that the maintenance of the destitute and their medical and surgical care are an obligation upon

the community. This obligation has been discharged more or less completely by means of private charity through endowments, or by local taxation. Only recently, and we must hope temporarily, because of the inability of these resources to meet the increasing demands occasioned by unemployment and depression has it been necessary to call upon the state and federal governments for financial support of these activities.

The official machinery of the community by which these responsibilities have been met has varied from the appointment of a city physician in the smaller communities to the establishment of Welfare Departments, overseers of the poor, and city and county almshouses and hospitals with medical officers on a full time salaried basis or giving only part time service with or without remuneration. In addition to these services for the indigent, organized public health departments have been established in cities and towns, as well as by the state to supply the needs of the community as a whole in the way of health administration, sanitation, the preparation of vital statistics, and quarantine measures in the communicable diseases. In many states however a considerably broader program has been developed by public health departments, involving health education, demonstration clinics, research in public health problems, the provision of biological products for therapeutic purposes, and similar measures. The maintenance of institutions for the care of the insane and of the tuberculous, although not as a rule directly under the supervision of the Department of Public Health represents another important and necessary medical activity of the local or state government.

The development of the public health services has been a gradual one and from its very beginnings it has been supported and guided by the medical profession. Of late years, however, there has been a disposition on the part of the profession to be critical of some, at least, of the more recent expansions in the field of public health, on the ground that the state was thereby entering into direct competition with the practicing physician. Where the practicing physician is properly equipped to give efficient service, such competition must be condemned and medical or surgical service by the state should be restricted to the indigent. Where such is not the case, however, no one is better aware than are the members of the medical profession that more efficient service made available by means of the financial resources of the state is to the material advantage of themselves and of their patients, and they are quick to avail themselves of these resources.

Neither physician nor layman will maintain that the public should be deprived of the opportunity for efficient service, when such service cannot be rendered by the practicing physician, except with the aid of those departments of the government which are concerned in the maintenance of the public health.

The problem of providing efficient medical and surgical service to the whole community is at the present moment seriously complicated by the deplorable ignorance of large groups of the population in regard to what efficient medical service really implies. The enormous sums expended annually for patent medicines and for the services of the quacks and cultists show that in many cases it is ignorance rather than economic conditions which lead people to such deplorable waste of their resources and of the opportunity to regain their health at the same time.

It must be clear to every one that it would be a waste of effort to make efficient medical and surgical service available to the whole community, unless or until the individual members of the community are sufficiently informed to make them ready to accept this service. At the present moment, while the demand is undoubtedly great, it is by no means universal. The ignorant and the credulous represent a formidable group throughout the country, and for their own sakes, as well as for the safety of the community at large, they must be educated rather than coerced to protect themselves. Today, with toxins and antitoxins, vaccines and serum tests, with insulin and other hormones and vitamins all based on accurate experimentation in the laboratories and with the X ray and other physical agents at our disposal, no one who is informed can doubt that physical, chemical and biological science is the foundation upon which the edifice of modern medicine has been constructed. This knowledge of the basic facts of medical science must be more widely published, in order that people may accurately estimate the futilities of the quacks and cultists, and the follies they advocate in the way of treatment of disease. Campaigns of public education of this nature can be carried out with propriety by the great national organizations of physicians and surgeons as well as by city, state and federal public health departments. The individual practitioner, who must restrict his part in public education to the instruction of his own patients, has the right to look to the larger organizations to fulfill this manifest public duty.

Just as the education of the public is a necessary feature of any project for providing more effective service to the whole community, so also is the

postgraduate instruction of the medical profession. Physicians and surgeons who are not in close proximity to the centers of medical education are of necessity limited by their continued occupation in competitive practice, by the paucity of their professional income, and by the great amount of charity service they now supply in their opportunities for postgraduate study. In a profession which advances as rapidly as does medicine, text books become out moded almost as soon as they are published. Medical journals and medical societies attempt to keep the practitioner informed of the notable discoveries of importance in medicine, but the practical estimate of the comparative value of these new developments is more difficult for him to obtain.

Of late years steps have been taken by a number of state medical societies to make available postgraduate instruction in medical and surgical subjects by bringing instruction to the physician instead of obliging him to leave his practice to go to some medical center to obtain it. Such plans are meeting a long felt want and give good promise of raising the general standard of medical and surgical efficiency but the needs for postgraduate instruction of the medical profession throughout the country are as yet but inadequately supplied.

From the point of view of their ability to pay for medical and surgical service, there are at least three classes of the community to be considered namely (1) the indigent, who cannot pay at all (2) those of adequate means who can afford to pay for what they need and (3) the intermediate group or those of moderate means who can pay for minor medical service but cannot unaided finance the expenses of serious illness or prolonged hospitalization within their restricted incomes.

The care of the indigent sick has long been recognized as an obligation upon the community and one which either through official sources or by private charity has, to a certain extent at least, been satisfied. So far as hospitalization and nursing care are concerned this is frequently the case, but all too often physicians and surgeons have been expected and permitted to contribute their services gratuitously for the care of this portion of the population.

The physician who serves the community should not be expected to stand in any different relation from that of other professional men who qualify for the public service. Except in teaching hospitals, where some equivalent other than financial return accrues to the physician or surgeon, in the way of reputation or opportunity his services should be paid for as are the services of lawyers,

engineers and other professional men who serve the city or the state.

Many communities already provide hospitals for the indigent sick maintained by public funds. When, owing to unusual circumstances such as those which exist today, the demand exceeds the accommodation available, such cases can very properly be accommodated in other institutions or in their own homes, and their care be paid for by the community on a cost basis and with a fee schedule for professional services on a minimum but reasonable scale.

Such a plan has already been authorized by the Federal Government for the medical care of dependents in the F. E. R. A. and the C. W. A. in their homes or in the doctor's office. While the many forms and records with which the government finds it necessary to protect itself are unfamiliar and annoying to the physician, an important principle has been established that the government recognizes its obligation to remunerate the physician who serves the community by taking care of the indigent, even though such remuneration is at present on a scale which must be regarded as a minimum.

The medical and surgical care of the well-to-do is reasonably well organized at the present time and no great modification of private practice as at present conducted, need be contemplated. It is undoubtedly true that very considerable expenses could be saved in caring for the well-to-do if they and their physicians and surgeons were disposed to eliminate some of the expensive laboratory tests, X-ray examinations and consultations which are so frequently demanded when their necessity is not apparent in the uncomplicated case. Such extravagances can only be avoided with difficulty if the patient is anxious to have them and pay for them but the physician is aware of the fact that the money thus expended would often provide needed hospital care for many patients in the lower income class.

The most difficult problem which presents itself in the organization of medical and surgical service to supply the needs of the whole community is presented by the great mass of the population which falls in the moderate means group. Individuals in this class can be independent and can select and pay for such medical service as they may need only so long as serious illness requiring prolonged hospitalization and continued medical or surgical care is not encountered. When serious illness does come, the middle class patient must either assume obligations in the way of debts which he can seldom discharge or he must lose his independence and become a burden on the

community. It is to this class especially that it has been proposed to apply the prepayment insurance principle in order to spread the expenses of serious illness over a period of small monthly payments for a number of years. It is a fact that health insurance in one or another form has been adopted as the most promising solution of the difficulties of this class of the population in some 40 countries in the world in the past 30 years.

Health insurance may be either voluntary or compulsory. In almost every other country the attempt has been made to start with a voluntary plan and it has been found necessary later to resort to compulsory insurance required by national legislation. This is not surprising when we consider the lack of knowledge of health matters, and the common characteristics of improvidence and lack of concern for the future which so frequently govern the actions of the human race. Some of these national insurance plans, as in Russia, involve the complete socialization and regimentation of medicine, a condition which is abhorrent to our western civilization. This is the form of medical practice which as *State Medicine*, with its inevitable political control and destruction of individual initiative is regarded by physicians as a menace to the best interests of the medical profession and of the community as well. Other plans, such as the British National Health Insurance Act, involve changes which are far less revolutionary and permit the medical profession to retain control of the medical aspects of the problem and to this extent at least, are looked upon with less disfavor by physicians who have made themselves familiar with the details of these different projects.

In a country composed of so many diverse elements as those which make up the United States of America with the population here crowded in great industrial centers, there scattered in agricultural districts and in other places more widely distributed still over the practically unsettled and frontier districts of the north and of the west, it is not to be expected that any single national plan for providing medical or surgical service to the whole community should prove everywhere to be satisfactory. The problem is essentially a local one to be studied and solved by the members of the individual communities and by trial and error if by no other means. In these experiments it is of vital importance that the medical profession should take the lead.

Already the Workmen's Compensation Laws of the several states require industry to apply the insurance principle to the medical and surgical

care as well as to the compensation of the injured workman, and the insurance principle seems to be in fact about the only way in which people in the moderate means class can be expected to pay either the hospital or the physician for the necessary costs of serious illness or operation. The machinery for the operation of the Workmen's Compensation Law is maintained by the state. In many states an insurance fund, operated by the state but contributed by industry, is provided as an alternative to commercial or mutual insurance. We must all believe that the principle of workmen's compensation for industrial injury and disease has come to stay. In many communities in this country experiments in the way of providing medical and surgical care on a prepayment insurance basis have already been attempted, and the results of their operation are being studied with the greatest interest. Most of the prepayment plans which have been put in operation have been started by industrial groups and involve a restricted territory and one of relatively uniform population. They vary from single group clinics to county medical society organizations. State wide projects of this character although proposed have not yet been put in operation. In order to escape the dangers of unfair competition, a plan should include all of the medical and surgical agencies of the local community that are qualified and willing to cooperate in giving such service. If too large the diversity of population and employment on the one hand and of medical resources on the other, may endanger the satisfactory operation of any plan. The American College of Surgeons has taken the position that prepayment plans of this nature should be "free from the intervention of commercial organizations operating for profit, in order that the maximum amount of the fund may be available for the payment of the medical, surgical and hospital expense which is to be supplied. Prepayment insurance plans not infrequently have been opposed by the medical profession on the ground that their operation in one way or another involves violation of the accepted code of ethics, especially in the matter of commercialism, advertising and unfair competition. That such dangers are present and must be avoided is clear to the physician or surgeon however difficult it may be for him to explain these objections to the layman. They rest in fact upon the experience of years of medical practice, and they are based upon knowledge of the weaknesses as well as of the stronger qualities of human nature.

The moderate means group which we have been discussing includes all those with incomes above

the indigent class and below the 'well-to-do.' It would not be unreasonable however to make a further subdivision of this large class of the community into at least two smaller groups—namely (1) those on the *lower level* whose resources even when they are employed, could not be expected unaided to provide, on a periodic payment basis, a sufficient amount to pay the cost of full medical and surgical service and (2) those of the *upper level* who can, through periodic payments, assure themselves of sufficient resources to obtain this service without resort to community help or public funds. The lower level group of the moderate means class are the members of the community for whom the provision of efficient service presents the greatest difficulties.

The difference between the amounts which individuals in this lower level group can pay and the actual cost of the service supplied, must be obtained from other sources. In this case as in providing for the indigent, the responsibility must devolve first upon the community. Many who now as indigents receive charity service undoubtedly belong really in this lower level group. A rigid investigation of their economic condition is necessary for their classification.

By virtue of the fact that the community is paying all of the expenses for the care of the indigent, and a proportion at least, of that of the lower level moderate means group the community itself should assume the responsibility for the quality of the service thus supplied.

The upper level group of the moderate means class may be counted upon to carry their own medical and surgical expenses provided hospital accommodation and efficient medical and surgical service can be made available to them on a basis of minimum fees. Within the past few years many hospitals have developed special intermediate wards for patients of this group where hospital expenses are reduced to a minimum by the elimination of non-essentials and a correspondingly reduced fee for professional service is collected by the hospital and paid to the physician or the surgeon in charge of the patient. Voluntary prepayment plans for hospital expenses or even for full medical and surgical service can undoubtedly be organized in connection with such services, and are greatly to be preferred to the present commercial health insurance projects which have been developed widely and have received such severe criticism in a number of states in the past few years. It is of great importance, however, that prepayment plans of this nature be not restricted to individual hospitals or smaller groups. They should be a *co-operative community organization*,

in order that all unfair competition may be avoided.

Great difficulty will be found in defining accurately in dollars and cents the limits of these different economic classes. Standards undoubtedly will vary from one community to another. Whatever criteria may be established in a given community in regard to this classification on an economic basis its observance should be rigid. One of the grave criticisms of the administration of our charity hospitals today is based upon the fact that the actual need for charity medical service is not always established beyond dispute in every case admitted to its wards. While the extent of this abuse undoubtedly varies considerably in different communities, those who seek undeserved free medical service at the expense of the truly destitute, must be meticulously sought out and prevented from obtaining such advantages. On the same basis the enjoyment of moderate means accommodations and reduced fees in hospitals should be rigidly restricted to those of limited resources whose finances do not permit them to obtain needed care in private practice.

The Medical Service Board of the American College of Surgeons has laid emphasis upon the necessity for strict observance of the code of medical ethics in the conduct of these new and experimental methods of supplying service to the community. In the consideration and evaluation of their success the medical profession must unavoidably be guided by the extent to which the new plans permit adherence to this code. Wide latitude is given however within these limits for the trial of such new methods of practice as may be suited to individual communities. The co-operation of the medical profession is essential to their successful operation and should be as freely given in this emergency as are their services on every other occasion where their need is manifest.

The co-operation of other groups than the physicians is also to be desired in consideration of these plans. Data of great importance have already been collected upon this general subject. The vast majority of the medical profession has hitherto paid but scant attention to great national social and economic problems. From the sociologists and economists much important information is to be obtained and a closer and more harmonious co-operation between these groups and the medical profession appears to be the great need of the present moment, in order that each may contribute of its knowledge to the solution of perhaps the most important question which affects the physical welfare of the community in the present generation.

In the Hospital Department of the American College of Surgeons we possess already an organization which is functioning in a most satisfactory manner for the survey of the hospitals by trained investigators. Through this department of the College accurate data in regard to such local prepayment or insurance plans as are now in operation or may be developed in the future can be readily obtained. It would seem at the present moment that the information we need upon which to base judgment as to their value can thus be secured at less expense than in any other way. It would be advisable, therefore to continue the collection of this information in order that it may be made available to those who are studying these problems.

The responsibility of industry for maintaining adequate emergency medical and surgical service for its sick and injured employees is at present widely recognized. The Board on Industrial and Traumatic Surgery of the American College of Surgeons has contributed in no small degree to improving the quality of this service by the establishment of minimum standards for industrial surgical services, based upon the fact that proper qualifications over and above those necessary for a state license to practice medicine, must be required of those engaging in this special form of surgery. The field of industrial medicine and surgery includes not only a consideration of the requirements of the Workmen's Compensation Laws of the several states, but as well a more extended program of medical and surgical supervision of the health of employees by physical examination, by study of the work hazards and requirements of the special industry by health education, and by the practice of preventive medicine.

Smaller industries and, in certain parts of the country, even those of larger size, have frequently chosen to entrust the risks and expenses of industrial accidents and workmen's compensation requirements to commercial insurance companies or "carriers" organized to assume these obligations. It is not unreasonable of course to expect that the responsibility of the insurance company, under these conditions, should become precisely that of the original employer so far as goes the obligation to supply adequate and qualified surgical service in the emergency treatment of the industrial accident case, and that in its subsequent supervision it should ensure that competent surgical care is given. The fact that either the employer himself or the insurance company which has accepted the responsibility for him is paying the expenses of such treatment and has a corre-

sponding interest in the successful outcome of the case, with a minimum of loss of time and a maximum of ultimate functional efficiency, justifies their insistence upon the adequate qualifications of the surgeons who give this special form of service. For the moment, the most practical way to secure these qualifications is to encourage those hospitals and those surgeons who desire to do this form of surgical work to meet the minimum standard established by the Board of Industrial and Traumatic Surgery of the American College of Surgeons.

With this necessarily brief review of some of the many different and somewhat conflicting factors which appear to demand consideration in any concerted movement to supply more efficient surgical service to the various economic classes of the population, we may well conclude that further information must be obtained by carefully organized and critically studied experiments before it will be possible for a final program of action to be prepared.

No single health insurance plan of national scope appears at present to be applicable to the conditions existing in this country. The matter is at present one for local study and experiment. In such a study the best medical and surgical ability in the community is needed, acting in co-operation with others qualified by their knowledge of economic conditions to join in the solution of the problem.

The provision of adequate service for individuals of the lower level income classes in the moderate means group, is the most difficult part of the problem. Some support derived from the community, to supplement any possible prepayment insurance plan, may possibly be needed to meet the requirements of individuals in this class. With further progress in health education those in the upper level of the moderate means class may well develop an interest and a desire to participate in voluntary prepayment plans, beginning perhaps first with hospitalization alone, and extending ultimately to full medical, dental and nursing services.

It is greatly to be desired that the trial of these new methods of providing medical and surgical service should be encouraged in different communities where the co-operation of the hospitals, the medical profession and others interested in the maintenance of the public health can be secured. Certain general principles which should be observed in the organization and operation of these plans have already been approved by the College. The Hospital Department of the College provides a ready means of securing accu-

rate information in regard to these plans and their operation, which should continue to be utilized to accumulate facts on which future judgment may be based.

While the advantages and disadvantages of the different plans for health insurance are under investigation in this laboratory of experience, a number of other steps are immediately open to us which should be of material help in providing more efficient service.

- 1 The value of the code of ethics of the medical profession in the protection of the interests of the whole population must be more widely appreciated by the public.

- 2 The medical and surgical care of the indigent sick must be recognized everywhere as an obligation of the community.

- 3 The segregation of hospital wards for patients of moderate means, who can and should

pay minimum hospital expenses and reduced fees, should be more widely practiced.

- 4 Abuses of hospital charity by those who can afford to pay must be prevented.

- 5 The expansion of the activities of public health departments into the clinical field should be restricted to demonstration clinics for educational purposes and to such other activities as can be made available to the community only by the use of public funds.

- 6 The education of the public in regard to health matters, and the postgraduate instruction of physicians should be more widely developed.

- 7 The quality of service supplied to the community should be recognized both by the public and by the medical profession as the first and most important consideration in every plan for providing more efficient surgical service and making it available to all classes of the population.

CANCER CLINICS AND CANCER SERVICES IN GENERAL HOSPITALS¹

ROBERT B. GREENOUGH, M.D. F.A.C.S. BOSTON, MASSACHUSETTS

FOUR years ago the Board of Regents of the American College of Surgeons announced its approval of plans for the development of special cancer clinics and cancer services in general hospitals. This action was not taken by the Board of Regents without due consideration of the presumed advantages as well as of the possible disadvantages of such a segregation of cancer patients from the general medical and surgical services of hospitals. Time has not yet elapsed sufficient for final judgment as to the value of these special clinics, but it would seem to be appropriate at this time to review some of the opinions which have been expressed in regard to the advantages and disadvantages which may result from their organization, and to consider to what extent their operation during the past 4 years has justified this recommendation of the College.

The report of the Committee on the Treatment of Malignant Diseases which was accepted by the Board of Regents and published in October, 1930, emphasized the fact that cancer institutes in which both clinical service and research were carried on simultaneously required such large endowments for their support as to prevent their establishment in any considerable number of centers throughout the country. It was recognized, however, that such institutes formed the most effective method of providing treatment for cancer patients who could obtain their services.

Special cancer hospitals, with adequate charitable endowment or supported by the state, were acknowledged to be the next most effective method of providing cancer service. Such hospitals may be expected to provide diagnostic and therapeutic facilities of nearly as high a grade as that of the cancer institute. They lack, however the generous endowment or other support required for the maintenance of laboratories and of the full time research staff qualified in the several different branches of science which are required to carry on effective cancer research.

The American College of Surgeons is concerned especially with the quality of service which can be supplied to patients with cancer and its recommendations were designed to improve this service. The vital necessity, however, for the continued laboratory investigation of cancer is acknowledged by surgeons as well as by all other physicians who have to deal with this disease.

The support of cancer research therefore both by persons of wealth who may be able to devote endowments or contributions to this most important field of investigation, and by the use of public funds, should be urged by every member of the medical profession as one of the most necessary fields for medical investigation. On account of the expense of construction and maintenance of cancer institutes and special cancer hospitals the fact must be accepted that a sufficient number of such institutions cannot at present be provided to take care of any considerable proportion of the cancer patients in the country.

Special cancer clinics and cancer services in general hospitals were next considered and because of the small expense involved in their maintenance and the fact that their organization permitted the same group method of approach to the individual cancer patient which has been the essential feature of the service given by the cancer institutes and special cancer hospitals the development of such special clinics in general hospitals was strongly advocated. As a matter of fact, two forms of cancer clinics in hospitals were recognized: (1) the fully equipped treatment clinic and (2) diagnostic clinics without complete treatment facilities. Both forms of clinics however employ the group method of study of cases. It was hoped that diagnostic clinics would be inspired to obtain the necessary professional experience and the material equipment to develop into treatment clinics, and be enabled thereby to give full service. In some instances this development has occurred, and if it were not for the difficulty in securing sufficient funds for the necessary equipment under these conditions of depression, such developments would probably have been possible in many other cases.

The Minimum Standard for Cancer Clinics in General Hospitals which was established by the American College of Surgeons includes six paragraphs dealing respectively with the details of organization, conferences, patients, equipment, records and treatment. The details of these requirements need not be repeated here. They can be secured by anyone who is interested from the office of the College and are already familiar to many who are present.

The situation may be briefly summarized, however, as an attempt on the part of the College to

¹ Presidential Address, presented before the Convocation of the American College of Surgeons, Boston, October 26, 1934.

procure more efficient care for the cancer patient by establishing the following general principle: The patient's interests are best served when the representatives of the several branches of medical science concerned in the study and treatment of cancer work together in a co-operative manner, instead of arrogating each to himself a limited field in which his own influence is paramount. That such a condition of individualism was almost universal a short time ago is abundantly proved by the publication in medical literature of many articles dealing with the treatment of cancer by writers who displayed so prejudiced a view in favor of their own special methods as to indicate conclusively their ignorance of the accomplishments of other branches of science in this extensive field. In this narrow attitude the surgeons have been perhaps the chief offenders, but intolerance of the views of others is by no means confined to surgeons; it is a common human failing but in this instance it may be overcome by the group method of co-operative study and discussion designed to provide for the cancer patient the most effective treatment which contemporary medical knowledge will permit.

The advantages to be secured by the establishment of cancer clinics in general hospitals may be listed as follows:

1. The patient receives more complete study and more efficient treatment.

2. More accurate and complete records are secured for subsequent analysis of end results with a view to the increase of knowledge. The use of the standard abstract record forms of the College assures more accurate recording of data, and a uniform system of classification for cancer in all of its more important situations.

3. The follow up of cancer cases after treatment is more systematic and contributes to the welfare of the patient as well as to the accumulation of more accurate knowledge.

4. Concentration of the cancer material of the hospital in the hands of a group provides greater experience for the individual members of the group and aids the development of their proficiency and productivity with resulting benefit to the patient, to the hospital and to the community.

5. The conference meetings of the clinic staff provide opportunity for more adequate undergraduate and postgraduate instruction in the subject of cancer and its treatment, and the reference of patients to the clinic by physicians in private practice permits the extension of this educational influence widely throughout the community.

6. The special cancer clinic provides a convenient and inexpensive method for supplying expert consultation service to aid the general practitioner and his patients in securing the diagnosis of cancer in its early curable stage.

7. Without material extra expense, and by mere rearrangement of services in the hospital in such a way as to entrust the cancer work to those who are more interested in this subject than in other special branches of surgical activity and are qualified to assume these responsibilities, opportunity for more efficient service to the patient is secured.

In order to estimate the extent to which cancer clinics in general hospitals have demonstrated their hoped-for advantages in the brief period since they have been in operation we must consider these seven items one by one.

1. The first item to be discussed and the one which is, and always will be, the most important, is the question as to whether the cancer patient does in fact obtain better treatment in the cancer clinic than under the old regimen. It would be indeed surprising if the opportunity provided for more careful study of the cancer patient by the group did not result in more accurate diagnosis of the actual stage of the disease. Cancer in its many situations presents a number of different paths of dissemination and frequently different sites of predilection for metastases can be recognized. Some of these peculiarities are characteristic of the histological type of tumor under consideration, and others are determined more by its anatomical situation. Thus the more experienced study of the group often discloses remote metastases which are positive contra indications to the attempt at radical cure of the disease by surgery and the patient is thereby protected from unnecessary operative measures which would be doomed to failure in any case.

The close association of the surgeon and of the radiotherapist in the cancer clinic permits them also to co-operate in providing more efficient palliative treatment in the advanced cancer case. The combination of radiation therapy and of surgical measures can frequently be effectively employed to bring about relief of distressing symptoms, and even to accomplish temporary arrest of the malignant process, with the result that the patient may live for a long period of relative comfort and even die *with* but not *of* cancer as a result of some intercurrent disease.

The early diagnosis of cancer is promoted, first, by the greater diagnostic experience of the special staff and, second, by reason of the possibility of exploratory operations, which can be performed

with safety in many instances only under restricted conditions, with competent frozen section diagnosis available and with the immediate completion of such radical operative or radiation treatment as may be indicated in the individual case.

Finally, only by consultation, such as is obtained between the surgeon, the radiotherapist and the pathologist in the clinic, can a wise decision be made in the many cases of cancer in which the choice between surgery and radiation treatment, or a combination of the two, is dependent not upon any general rule, but rather upon the conditions existing in the individual case.

Such considerations as have been mentioned are, however, still somewhat theoretical and the real test as to whether the cancer patient obtains more efficient care must be determined by the attitude of patients and of their medical advisers toward the services of the clinics. Everywhere the attendance at cancer clinics is on the increase. In some hospitals in which the reference of patients within the hospital is voluntary and not obligatory, the attendance at the cancer clinic has been steadily increasing year by year. There were 14 cancer clinics in the country in 1920 and they were chiefly in cancer institutes. In October 1933, there were 158 approved by the College, and some 155 in course of organization or awaiting survey. Such a development must indicate that the belief is widely held that through the organization of a cancer clinic, the patient obtains more efficient treatment.

2. That the establishment of cancer clinics leads to the making of more accurate and complete records of cancer cases can hardly be denied. No one who has looked up hospital records of 10 years ago with the object of studying a group of cancer cases, but has discovered many individual records so lacking in the data now considered essential in the way of history, physical examination, pathology, and details of treatment as to be of no value whatever for classification or analysis. With the interest of the special group composing the clinic staff in preserving accurate and complete records, and with the aid of the standard abstract record forms prepared by the College, the records of cases in the cancer clinics have been greatly improved. The element of uniformity alone obtained by the use of the standard abstract forms is a material advantage since a uniform method of recording and of classifying cases permits the collection of data on a much wider scale than heretofore, by the assembly of records from many different clinics, and makes possible a

justifiable comparison of the end results of different forms of treatment which we have not had before.

3. Twenty five years ago no hospitals anywhere had a systematic follow up system of all their patients and in only a few institutions in this country—and usually then only at the instigation of some interested member of the staff—was any effort made to maintain a continuous investigation of the long time end results of the treatment of cancer. Dr. E. A. Codman's crusade for the more general adoption of end result studies in hospitals is well remembered by the older generation of surgeons today, and has borne fruit in the widespread development of follow up clinics in general hospitals all over the country. In spite of the gradual adoption of these principles, however, the long time continuous follow up of cancer patients has not even yet been universally adopted or vigorously carried on in general hospitals. Such a follow up, however, is an essential feature of cancer clinic service. The advantages of such a continued interest are readily appreciated by the patient. Appointments for follow up visits are seldom broken, and only rarely is it necessary to call upon the social service department for home visits and further investigation. The present knowledge of the end results of the treatment of cancer on a minimum 5 year basis has already made possible the collection by the College of an enormous number of 5 year cures of cancer, a movement which has done much to dispel the pessimism of the public as well as that of the medical profession in regard to the possibilities of the successful treatment of this disease.

4. The concentration of the cancer material of the hospital in the care of a relatively small group gives opportunity for a much richer experience and increased opportunity to the individuals selected for the cancer clinic staff. It is not unreasonable, of course, and rather is it to be expected, that this special assignment of privileges to one group shall be compensated by similar assignments to other groups of other branches of special work, such as fractures, circulatory disease or similar subjects of special surgical interest, as a *quid pro quo*. Such assignments may be only temporary and a certain amount of rotation of privileges of this sort is often advisable in the case of junior members of the staff.

The surgeon who receives an assignment to a special clinic, whether it be by the direction of the chief surgeon of the hospital or by the decision of an executive staff committee, should accept it as a privilege, which it becomes immediately his duty to justify. Such justification must be dem-

onstrated not only by the increased efficiency of service given to the patient, but by such study and investigation of the hospital clinical material, as will add to the professional reputation of the institution.

5. The essential feature of cancer clinic organization is the group attack upon the cancer problem. The group must include primarily one or more representatives of each of the three special branches of medicine which are most intimately concerned with the study and the treatment of cancer: surgery, pathology and radiotherapy. Each of these different individuals brings to the group study of the cancer patient special knowledge and experience which has been acquired only through a long period of study of these special lines of medical science.

Until the group study plan was inaugurated prejudices and misunderstandings extending even to bitter accusations of violation of the ethical principles of medicine were not uncommon among the representatives of these different specialties concerned with the treatment of the cancer patient. It is extraordinary to observe the readiness with which such biased judgments disappear when free expression of opinion and experience can be secured in personal conference over the problem of the individual case.

Such conferences are first and foremost of advantage to the members of the group on account of their educational effect, but this educational advantage is by no means confined to the individuals participating in the discussion. It extends immediately to the junior attendants, internes, medical students and nurses who are connected with the clinic, as well as to members of the general hospital staff and to physicians who desire to attend the conference as visitors, in order to keep in touch with progress in the diagnosis and treatment of cancer.

A further extension of the educational influence of the cancer clinic is the practice prevalent in many clinics, of encouraging the physician who refers his patient for advice to come to the clinic with the patient and share in the group discussion of the case. When this is impossible a letter is usually written to the physician who sends his patient to the clinic giving the full details of diagnosis and of the treatment advised. Such measures not only extend the educational influence of the clinic, but they also procure the co-operation of the physician in the subsequent follow up of the patient to the advantage of all concerned. In fact the educational advantages of cancer clinics are so readily appreciated as to be hardly open to discussion by anyone familiar with their operation.

A cancer clinic in a general hospital provides expert consultative service at a minimum expense to the medical profession of the community. The difficulties encountered in the diagnosis of cancer in its early and local stages are widely recognized. The general practitioner without the experience or the equipment to solve these problems is further handicapped in dealing with a doubtful case by the fact that he cannot afford to get the reputation of being an "alarmist" neither does he wish to refer his patients unnecessarily for consultations involving loss of time and travel expenses as well as heavy consultation fees. For reasons such as these, he is tempted to delay. Unfortunately this delay may be of vital significance in determining the success or failure of treatment in the individual case which actually proves to be cancer. When consultation involves merely a visit to the nearest general hospital with a minimum of expense and loss of time, this occasion for delay is done away with to the advantage of the patient and of his physician as well.

From the point of view of economy there is no doubt that the cancer clinic in the general hospital has advantages that are not to be gainsaid. It provides within the limitations of the professional ability of the staff and of the equipment of the hospital, a service patterned on that of the major cancer hospitals and institutes. This is accomplished by the simple re-assignment of the services of the hospital staff and a corresponding classification and redistribution of its patients.

In the surgical staff of every hospital there are some surgeons who are interested in one phase of surgery and others in another. Such interests are recognized by every chief surgeon in the assignments he makes of the hospital material. The establishment of a cancer clinic is but a slight extension of this plan, involving the participation of the staffs of the surgical, the pathological and the radiotherapy departments and of suitable representatives of other services, such as medicine, gynecology, genito-urinary surgery, otolaryngology and dermatology. The co-operation of the neurosurgeon, the orthopedic surgeon, and the dentist is also much to be desired. The only extra expense the hospital need consider is the provision of suitable space for examining rooms and for clerical and social service workers, and a convenient conference room. The salaries for clerical and social workers must, of course, be included. Most general hospitals are already equipped with all of the surgical instruments and apparatus required for the diagnosis and treatment of cancer and many have excellent X-ray equipment for therapy as well as for diagnosis. In some hospitals radium

in sufficient quantity is already available for treatment. Where this is not the case the greater expense of purchase of radium must be considered or the need may be met by arrangements with other institutions. When such facilities are already available in the hospital, the expense involved in the organization of a cancer clinic is thus a minor consideration.

The principal disadvantage which has been claimed to result from the organization of a cancer clinic in a general hospital, is that the segregation of the cancer cases and their removal from the general medical and surgical services diminishes the interest and the experience of physicians and surgeons on these services and tends to restrict the treatment of cancer to a limited group of specialists. This disadvantage must be admitted in regard to cancer as it is admitted also in regard to orthopedic surgery, genito-urinary surgery, gynecology, neurosurgery and a number of other special branches of surgery and of medicine which have developed and flourished as a result of the rapid advance of medical science and the virtual impossibility for any single human mind to acquire and retain in serviceable form the amount of knowledge which has resulted from the medical progress of the past 50 years. The day when one surgeon or one physician could make himself master of all of the information needed to deal efficiently with every variety of disease which may present itself has long since passed, and specialization is the answer to this condition. It is through specialization indeed, that many of these same advances in medicine and surgery have been brought about. Specialization is the price we of this generation are obliged to pay for the benefits we have obtained from the progress of medical science in the past 50 years. Not only must we believe that specialization has come to stay but we must recognize that its further development is imminent. Even in this special subject of cancer further limitations of the general field are already evident in the subdivisions of interest and of experience on the part of the individuals who are united in the cancer clinic staff. The special interests and the special qualifications which determine these subdivisions of the work of the cancer clinic are to the positive advantage of the patient as well as of the staff. It is a form of voluntary division of labor which yields most

desirable results. Such division of the work of the clinic may be only temporary and elastic and rarely need be extended beyond the hospital, but an established reputation along some special line inevitably brings the demand for consultation service from professional colleagues. This subdivision of the work of a cancer clinic is further an economy of time. In clinics which are open every day one day of the week may be devoted to one group of cases and the next day to another to the obvious advantage of conservation of the time and energy of the staff and the avoidance of undue delay on the part of the patient.

Another objection which has been raised against the organization of these special clinics is that the term cancer creates apprehension and sometimes despair on the part of some of the patients who may be advised to come to the clinic for consultation. This feeling is so strong in certain communities that the alternative term of "tumor clinic" has been employed as an euphemism, although the clinic carries on exactly the same functions under either name. As a matter of fact the progress of public education has already brought about a change of attitude on the part of the public toward the term cancer. The subject is discussed more freely and with far less apprehension than was the case 20 or 30 years ago and this supposed disadvantage will probably disappear entirely in a few years more. If not, the use of the term tumor clinic is an easy remedy.

In conclusion, we may say that the suggested disadvantage involved in the organization of cancer clinics in general hospitals—that it tends to make the treatment of cancer a specialty—must be admitted. It does and it does so intentionally, but it is a group specialty, not an individual one. There is abundant evidence that under the group method of study and of treatment the patient the physician in general practice, the surgeons of the country and the community itself believe that the cancer patient receives more efficient treatment. We may conclude therefore, that there is no occasion at this time to alter the policy of the American College of Surgeons of advocating the organization of cancer clinics in general hospitals. Rather should this policy be re-affirmed and efforts be made to aid these clinics in every way to provide still more efficient service to the cancer patients seeking their help in the years to come.

MEDICINE AND PUBLIC SERVICE¹

L. D. COFFMAN, PH.D., LL.D., MINNEAPOLIS, MINNESOTA

Paul Scott, University of Minnesota

NO progressive person would return to a simpler life with its primitive practices and superstitions if he could. With all of the complexities and difficulties arising out of a constantly expanding civilization, we should prefer to face its problems and to deal with its complexities rather than return to ignorance and superstition in dealing with the issues of life. Every civilization in the long run pays for what it does not have as truly as it pays for the things it possesses, but it pays for the things it does not have with a different kind of coin than it uses in paying for the things it does have. Ignorant and backward nations pay in poverty, destitution, unborn hopes and ambitions, ignorance and unnecessary sickness, for the scale of civilization that they maintain. Under such conditions the demagogue finds the ignorant populace an easy prey to his nefarious schemes. The practice of the various professions, such as medicine, law, the ministry, and education is necessarily on a low level under such conditions. The progressive development of the well-being of a people calls for sacrifices in effort and money. Every step forward taxes the ingenuity of the people, lays necessary tribute upon their resources, and calls for an increasingly superior quality of service.

What is true of nations in general is likewise true of groups that are responsible for the advancement of their professions. It is true of the medical group. No one would have medical practice revert to the days when we knew nothing of vitamins, of radium, of the roentgen ray and radiant energy, of the chemistry of drugs, of the use of serums, or of modern surgery. We are well aware of the fact that contributions to medical knowledge in the last sixty years have exceeded in number and significance the contributions of the preceding three or four thousand centuries, and we have only begun. What lies ahead is entirely in the lap of the gods. It depends to a very large extent on the attitude that we take towards science. This is no time to be talking about science taking a holiday. Indeed the cure of human disease, the alleviation of human suffering, the prolongation of human life—in fact, all those things which contribute in any way to physical and mental health are directly dependent on the further advancement of science. Science cannot halt nor falter in its work, it must study

every change in our social and industrial order for every change probably creates new diseases, changes certainly modify conditions affecting old ones. Practically every step forward in the march of civilization has been marked by some discovery, some invention, and by the extension and distribution of human knowledge. Mankind is engaged in a continuing process of regeneration; each regenerative step is simply another mile stone in human achievement.

The representatives of the medical profession have certain responsibilities and obligations in common with the representatives of all other professions. The two chief responsibilities that they have are namely, to advance the basic knowledge and the craft spirit of their own profession and to promote the common welfare. The advancement of the interests of one's own profession is best performed by devoting oneself to his profession. Simple as this seems to be, it is not always done. Too many lawyers, too many teachers and too many doctors worship at the shrine of their avocations rather than at the shrine of their vocations.

From observations ranging over more than forty years in the educational field I am of the opinion that the surest way for a scholar to win recognition is to become a better scholar; the surest way for a lawyer to become distinguished is to become a better lawyer; and the surest way for a doctor to achieve success is to become a better doctor. Obviously one cannot become a better scholar, a better lawyer, nor a better doctor except by devoting himself diligently and faithfully to his profession—all of which means that he must, among other things, study and master the new knowledge appearing in his field.

It is true of course that there are a number of factors that make this extremely difficult. One is the growth of knowledge itself. It is now extremely difficult, if not impossible, for one to know everything about a given field of learning, but in so far as it is possible, surely there rests upon the professional man the obligation to be the master of the things that he professes. Another factor that makes it difficult for him to achieve this ambition is that in recent years there has been a tendency to subdivide knowledge and to differentiate and specialize practice. Partitioned practice in the field of medicine certainly

L. D. Hoffman

has earned with it all of the weakness of specialization in general and has greatly increased the costs to the patient.

If I may be permitted, I shall cite one personal experience which illustrates what I mean. I realize of course, that this experience may be a little extreme and that it may not have been possible for these events to happen in any other part of America. Some years ago, when I was in another state, I was suffering from some throat trouble. I was anxious to find out what the source of the trouble was and if possible to have it remedied. I called on a certain doctor who was a member of a certain clinic and who had a long printed form consisting of some two hundred questions which I was required to answer. These questions asked for far more detailed information than I would be expected to give in case I were applying for insurance; they not only went back to my immediate ancestry, but to my grand ancestry and my great-grand ancestry. All of my habits of life were minutely inquired into. After this man had secured a complete inventory of my ancestral history, of my physical weaknesses and of my opinions on all sorts of subjects, he very wisely informed me that he would now take time to examine his report more carefully, but in the meantime he would pass me on to Dr. So-and-so, with the suggestion that this doctor examine my tonsils. Dr. So-and-so placed a long slender piece of larch board down my throat, required me to say "ah" in a half dozen different languages and finally decided that a culture should be taken of the tonsils, but that he would not have it done that day. He did pass me on to a third doctor to have my teeth roentgenographed. When this man had completed pictures of all my teeth, he said, "I never pass judgment on the pictures. I only take them." That made it necessary for me to see another doctor who decided that one of my teeth was ulcerated at the roots and that it should be extracted. Still being unsophisticated in the ways of the medical and dental professions, I went unsuspectingly to this fifth doctor who proved to have an expert assistant. This man gave me some sort of gas, and while I was under the influence of it the offending tooth was removed. Upon my returning to consciousness this doctor said to me, "That was a very difficult tooth to remove. You have a badly lacerated jaw; it will now be necessary for you to have it treated for several days by Doctor —." Then the explosion occurred. I raised the roof. When I received a bill for the services that had been so generously given me during the afternoon, it was for \$125.

I do not recite these facts to condemn the medical profession, only to show what kinds of unfortunate practice may creep in, partly because of the differentiation of knowledge and partly because of blind obedience to the god of specialization.

Clearly there is need for the co-ordination of work among specialists in every organization. Surely one who distrusts a person's lower maxillary should know enough to treat it afterwards. Medical practice cannot be standardized in the way in which industry can be, nor can operations be performed on a mass production basis, but when a doctor confines his practice to the winking muscle of the left eye he is really going too far.

While the surest way for an individual to advance himself in his profession is to become more professional, the surest way for any group of specialists in a profession to advance themselves and the interests of their profession is to co-ordinate and to organize their activities so as to insure the fullest, freest, and most intelligent co-operation.

Any profession that is constantly advancing will find it necessary to raise its standards from time to time. The people of a country have a right to improved service. Not only must there be a raising of standards, but means must be provided for the continuing development of those engaged in practice.

I am not much concerned about the number of doctors that we have. I know there is a vast amount of talk among the members of your profession as to whether there is an oversupply of doctors. Figures are cited to show that we have about one physician to every 750 or 790 persons in the United States and that this is a larger number than is to be found in England, Germany, France or Sweden. It is believed that the presence of so many practitioners is in itself a weakness because it leads to unfair and unprofessional competition.

I recall another circumstance which I think has a definite bearing on this particular matter. About ten years ago I was invited to be a lay adviser of one of the great foundations of this country in connection with certain projects that it proposed to make in stimulating a public interest in personal and community health. We proposed to go into a number of communities, some urban and some rural, in various sections of the country, with a view to testing out our theories. When it was announced that we expected to go into a certain city, a city of about 40,000, every doctor in town I think, joined in a protest against our coming. We were as unwelcome as Mr. Hoover would be in Mr. Roosevelt's cabinet. No doctor

wanted us. But not fully understanding the medical mind we went into the community nevertheless. We took a group of trained nurses and competent doctors into the community. The nurses began having conferences with expectant mothers and with mothers of infants with regard to prenatal and postnatal care of children. The doctors began having meetings with small groups here and there at which health score cards and charts were devised for the school children. The nurses and doctors who represented the Foundation were persons of rare intelligence and attractive personalities; they were adroit and skillful in meeting people and in discussing matters with out offending them. At the end of the year the local medical society which was composed of all of the doctors in the community had a meeting and passed resolutions requesting the City Council to levy a tax which would be the equivalent of fifty cents on every person in the community to maintain the service which we had established. What was responsible for this change of heart and mind? The doctors said that there had been no reduction in their business during the year as a matter of fact, it had increased; their incomes had increased and, furthermore the quality of their work was much higher than it had been a year before more persons were coming to them asking for advice, seeking examinations in matters relating to their health and that of their children. The modern knowledge about diagnosis, treatment and prevention of human disease which had been dispersed by these unwelcome guests, had raised the quality of medical knowledge and of medical practice to a higher professional basis than ever and the doctors were happy.

Some five years ago while in Russia, I visited a number of clubs that had been established for laboring people. I remember one in particular where there were about one hundred men and women—peasant men and women—listening to a doctor who was talking to them about the simplest things relating to their own health and that of their children, and their responsibility for the health of the community. The vacant expressions of these peasant men and women began to light up as they began to understand a little here and there about the things the man was discussing. It was the first time in their lives that they had ever received any instruction along these lines. This campaign for the diffusion of learning bearing upon physical and moral health, has been carried on widely throughout Russia.

It is my opinion that every time we raise the cultural level of a people we increase their wants, we multiply their needs we fructify their ambi-

tions. Perhaps the medical profession should take steps to request that none except those who possess adequate ability should be permitted to enter upon the study of medicine, and that none except those with the highest ethical ideals should be permitted to engage in the practice of medicine. But one of the surest ways of solving the over supply problem in this, as well as in every other profession, is to educate the people with regard to the service the profession can render.

Then another one of the problems with which the medical profession is gravely concerned is how to distribute medical services so as to care for large numbers of people. We hear this movement referred to as a movement for socialized medicine. It manifests itself in various forms in some countries in the form of insurance. In others the government subsidizes medical practice in certain areas. In some instances individuals within a community engage a community doctor and voluntarily levy a tax upon themselves and in others, corporations, manufacturing concerns, and business enterprises of one kind or another engage doctors to care for their employees. The thing that we shrink from in America apparently is the use of the term "socialized or state medicine." It is anathema to many. When Dr. Angell of Yale spoke before this convocation, he said that we should not be disturbed by a name. He advised us to look carefully into the matter and to make our decisions on the basis of facts and the quality of service that we should undertake to render. In our antagonism to a point of view regarding a form of practice, we must not overlook the fact that the recruiting officers of state socialism are want, restlessness, and despair nor must we overlook the fact that we have many socialistic institutions and socialistic forms of control in America. The American public school system, for example, is the greatest socialistic experiment that the world has ever witnessed. Our fire departments, our police systems, our post offices, are examples of pure socialism in government.

The American people are practical people; they are constantly seeking something that works; the test of its success is the quality of work that it performs. The American people are distrustful of abstract ideas, abstract political theories, abstract social theories; they aim to take the course that works best in actual practice. For that reason there is a mixture of every form of control in America—democracy, communism, socialism, constitutionalism, autocracy, dictatorship—each in turn under differing circumstances, has been approved and has been accepted when the motives

were found to be good motives and the practical results were proved to be good results. Human life is so varied, its problems so complex and so numerous that they cannot all be forced into a strait jacket of any single theory. Just as good government will use many methods, every method depending upon the circumstances, to advance human welfare, so professional groups likewise must have a pragmatic philosophy, changing their methods when changes will produce better results.

Nor must we overlook the fact that the masses everywhere are demanding greater opportunities and a larger share of the comforts of the world. They want good government, employment, old age insurance, unemployment insurance, education for their children, and the opportunity to live healthful, wholesome lives. They are trying to fashion a new philosophy in a world that is still held in check by administrative practices, modes of procedure, and outlooks of another day. The American people want to be shown that the things they desire cannot be attained. The important thing about our people is their common sense: they believe that the world is not finished, they think it is still advancing, they are willing to experiment with methods and processes and forms of organization of a humanizing and socializing character. They are not ready to accept these things wholesale, but they are willing that they shall be tried.

Wherever people under existing conditions cannot obtain the benefits of modern medicine, there is a serious gap in the distribution of this service. To this extent civilization fails. Either we sit back and acknowledge the problem as insoluble or, regardless of preconceptions or alogans, we seek a practical solution. If the solution calls for some changes in the traditional way of distributing medical services, we shall allow need and service to guide our practices rather than tradition or selfish interests.

Doctors live to serve others. The relationship between the doctor and the patient is intimate and personal. That is the real reason why we shy at systems, codes, and forms of political control. Should the politician stand between the patient and the doctor, both the patient and the medical service would suffer. It requires a powerful idealism on the part of the community and great strength of character on the part of the individual to sacrifice political ambition and personal ideals for the common welfare. No people has ever done it to any considerable extent or for any long period of time and yet every people is constantly trying to achieve this goal. Sacred

covenants and promises to act collectively in the common interest, even when communities or professional groups have been operated under the inspiration of a moving religious principle, have often vanished as disillusionment has entered the souls of such communities or groups. Perhaps it is ease and material prosperity that dulls our hopes and darkens our ambitions and makes us cling to traditions. Perhaps after all there is something fine and subtle in human nature—a native inherent unspoken hope to live one's life in the manner in which he thinks he can best serve others, that lures one on to greater achievement. No one would wish to curtail idealism of this type. Great individuals, whether inside or outside an organization, will achieve to serve and serve to achieve.

It must be true indeed that the life of every organization comes at last to depend on those few who do the work and who actually put their hearts into it to maintain that solidarity of interests that is essential for the preservation of the ideals of the craft. On the other hand, I know that there is always present in every craft an inevitable minority who through indifference, lack of responsibility, selfishness or a desire to live softly, refuse to meet their moral obligations or their covenants. These obstructionists will not survive, for life is being tested more and more by spiritual standards. The world will reward those who show a willingness to lose themselves in some great cause or in some glorious adventure. The true heroes of a profession are those who have truly kept the faith, those who seek opportunity in order that they may fulfill it. Without thought of personal reward or private gain, the gifted few in succeeding generations, with luminous sincerity and a grave sense of responsibility, have taken the torch from falling hands and held it high. The true torch-bearers of a profession are the unrecognized "millionaires of the spirit" who have ever placed the welfare of the community above personal preference.

So I should say upon this occasion that the things that we desire to have and to hold in every profession are first, personal freedom, which carries with it the responsibility of discharging to the utmost of our ability our individual obligations, second, the interests of common welfare which means upholding the ideals of a group and third, social good which means that we should give freely of our talent and skill in the common interests, no matter under what kind of administrative program we may be working.

PRESENTATION OF HONORARY FELLOWS

FRANKLIN H MARTIN M.D. F.A.C.S. CHICAGO, ILLINOIS

AT the Convocation on Friday evening, October 19, Honorary Fellowships were conferred by the President on the following eminent surgeons:

Sir Harold Delf Gillies, London, England—Commander of Order of the Bath of England, Commander of Order of the Dannebrog, Knight Bachelor, Fellow of the Royal College of Surgeons of England, Plastic Surgeon to St. Bartholomew's Hospital. Introduced by Vice President Charles A. Duken.

Professor Josef Halban, Vienna, Austria—Doctor of Medicine and the Distinguished Professor of Gynecology in the University of Vienna. Introduced by Regent Richard R. Smith.

Mr Harry Platt, Manchester, England—Doctor of Medicine, Master of Surgery, Fellow of the Royal College of Surgeons of England, Lecturer in Orthopedic Surgery at the University of Manchester and President of the British Orthopedic Association. Introduced by Regent John R. Fraser.

Dr Bethel Solomons, Dublin, Ireland—Doctor of Medicine, Fellow and former Vice President of the Royal College of Physicians of Ireland, Examiner in Obstetrics and Gynecology, Royal College of Physicians and Surgeons of Ireland and in Dunham University. Introduced by Regent C. Jeff Miller.

PRESENTATION OF CANDIDATES—CLASS OF 1934

FRANKLIN H. MARTIN M.D. F.A.C.S. CHICAGO, ILLINOIS

IN behalf of the Board of Regents of the American College of Surgeons, I have the honor to present for Fellowship in the College candidates as follows:

United States	567
Canada	13
Nicaragua	1
China	3
Chosen	3
Bahamas	1
England	1
India	3
Syria	1
Turkey	1
Total	590

Each year as we receive a new class of candidates into Fellowship I am impressed by the prestige of an institution that can influence such a goodly number of busy practitioners of surgery to seek its portals.

To the casual observer these men and women appear as one more group that is being enrolled into our ranks. Complacently this observer shrugs his shoulders and reflects "How easy!"

As an illustration let us enumerate the facts. There were 4,988 applications for Fellowship on file January 1, 1934. One thousand one hundred and twenty-six of them were already ap-

proved by their State or Provincial Committees on Credentials. 1,673 were presented to State and Provincial Committees on Credentials during this year. Of these only 639, or 38.2 per cent, were approved and recommended for examination. Of the total recommended for Fellowship before and since January 1, 1934 (1,765) our careful sifting process has admitted to Fellowship only 590, or 33.4 per cent, constituting the candidates who are here present. Of the total 4,988 applications that were on file January 1, 1934, the 590 accepted candidates represent only 11.8 per cent approved, or 1 in every 8 applicants.

Surely if we pay tribute where tribute is due we must pay full portion to the magnificent group which is before us this evening. Veritably they are the survival of the fittest.

They are to be congratulated and the College is to be congratulated but above all, we must congratulate the people who shall in the future seek their services.

Mr President, inasmuch as the candidates herewith presented have fulfilled all of the requirements for admission and have affirmed the Fellowship Pledge of the American College of Surgeons, on authority of the Board of Regents of the College, I take great pleasure in presenting them for Fellowship.

CASE HISTORY HONOR LIST AND PRIZE AWARD

ALLEN B. KANAVEL, M.D. F.A.C.S. CHICAGO ILLINOIS

THE Editorial Board of SURGERY, GYNECOLOGY AND OBSTETRICS is so heartily in sympathy with the program of the College and its demands that all patients should receive careful study, as evidenced by adequate records, that in 1930 it asked of the Board of Regents the privilege of presenting an annual prize in the form of a life Fellowship in the American College of Surgeons for the most acceptable set of case records presented by the candidates during the preceding year. The prize consists of five hundred dollars invested in the name of the successful candidate for life dues in the American College of Surgeons, and is accompanied by an appropriately engraved certificate of appreciation on behalf of the donor SURGERY GYNECOLOGY AND OBSTETRICS.

The prize winners of the last 4 years have come from Louisiana, Texas, Montana, and West Virginia respectively.

Forty five histories, outstanding because of their evidence of careful study of the patient, have been selected. These were examined by the full Committee on History Reviews of the College with the name of the surgeon and his address eliminated so that an unbiased choice might be insured. Five sets out of the 45 have been selected as the best and the authors of these records

placed on an honor list. May I ask each honor man to rise as his name is read.

Nicholas Gotten, Philadelphia Pennsylvania
Wallace L. Nelson, Wisconsin Rapids Wisconsin
Roscoe W. Teahan, Philadelphia, Pennsylvania
Harry V. Thomas, Fairmont West Virginia
Clarence H. Snyder, Ann Arbor, Michigan

On behalf of the College I extend to each of you the congratulations of the Board of Regents upon the excellence of your case histories. And now, may I announce the prize winner from among this group and invite him to the platform to receive the certificate of appreciation from our official journal and the formal receipt for life dues in the American College of Surgeons?

Will Dr. Snyder please come to the platform? Dr. Snyder, this recognition of your work is an expression by the College of its belief that scientific investigation, careful records and critical analysis of case history elevates the standard of surgery and insures to patients the most efficient care. It is our hope that this expression of commendation may serve to stimulate others to emulate your example, advance the frontiers of surgical knowledge, and benefit those entrusted to our care. I congratulate you.

SYMPOSIUM CANCER IS CURABLE

THE CURABILITY OF CANCER¹

FRANKLIN H. MARTIN, M.D., CHICAGO, ILLINOIS

Director General, American College of Surgeons

MAY I cite briefly the objectives which were in my mind when this yearly Symposium on the Curability of Cancer was established in 1932? Through the reports of cancer cures that will follow it is my hope

1. To impress upon the practitioners of scientific medicine, and indirectly upon the public, the fact that carcinoma is curable by the use of well known and established methods of treatment.

2. To point out in a convincing manner that if all cases of cancer could be diagnosed early and treated promptly in their incipency the annual death rate from the disease, now recorded as 150,000 in the United States and Canada, would be reduced by at least 33 per cent, or 50,000 per year. Even if only one half of the cancer cases could be diagnosed early and properly treated, the death rate would be reduced by 25,000 per year.

3. To bring together the group of distinguished clinicians who reported in 1932 and 1933 and those who are here present—an overwhelming authority—to present definite statements of the impressive number of cases of cancer that have actually been cured. This preponderance of evidence, so convincing as an object lesson, will impel ever increasing numbers of the people to demand facilities, through scientific doctors, for annual or semi-annual examinations, so that not only cancer, but any and all diseases may be discovered in their incipency when they are amenable to treatment.

4. To secure the maximum of ethical publicity of the reports. This will furnish convincing evidence to our hospitals, our local medical societies, and our already established clinics, and encourage them to furnish facilities whereby every physician who is practicing scientific medicine will have available the necessary equipment and trained aids to insure the comprehensive examination of his patients.

5. To convince the profession and the public that even though cancer is already apparently in a later stage of its development, if it is subjected to proper treatment, its progress may often be

delayed, and the disease not infrequently cured to make these facts so obvious that a general policy will be established to treat systematically every case of cancer in whatever stage of advance, not only because of the immediate or remote possibility of a cure, but because palliative measures would bring great relief of distressing symptoms, and encouragement instead of forlorn hope.

6. To establish a universal policy among physicians and surgeons to report *cancer cures* rather than to present the involved comparative statistics that dwell particularly on the cases not cured.

If we here present accomplish the full humanitarian purposes for which this yearly symposium

CANCER CURES—1932, 1933 AND 1934

Cervix	453
Fundus	1,103
Ovary	555
Vagina, vulva, perineum, and urethra	13
Breast	6,457
Mouth and lip	2,351

Bone	91
Upper jaw and antrum	127
Lower jaw	90
Others	75

Grand total cancer cures 5 years and over 24,440

NOTICES OF CASES REPORTED

Reported at Clinical Congresses prior to 1934	70,534
Registered cases at American College of Surgeons	1,320
Reported at 1934 Clinical Congress	2,077
Total	24,440

¹The total figure is not larger than reported in 1933 on account of the elimination of individual cases which have been reported previously by more than one author.

¹Presented at the symposium, Cancer Is Curable, before the Clinical Congress of the American College of Surgeons, Boston, Oct. 2nd-7th, 1934.

was organized the discouraging psychosis that now exists in the minds of the profession as well as the public will be dispelled, a consciousness that cancer is curable will be established in the

minds of all, fear will be displaced by a spirit of hopefulness, and every victim of cancer or suspected cancer will present himself or herself for early diagnosis and treatment.

CANCER SURVIVALS, WITHOUT RECURRENCE, OF FROM FIVE TO TWENTY-FIVE YEARS¹

ROBERT SPANN CATHCART M.D. F.A.C.S. CHARLESTON SOUTH CAROLINA

THIS short résumé of malignant tumors falls roughly into two logical classes. Class I consists of the cases treated in the Roper Hospital, the teaching hospital of the Medical College of the State of South Carolina, which cares for the indigent sick of Charleston—city and county. The patients in this class were seen and attended by some dozen odd surgeons including the author. Class II consists of the private cases of the author that were attended in various other hospitals.

A factor that must be constantly borne in mind in evaluating the statistics is that all of the patients in Class I were free bed cases, most were from the lowest orders of society, and many presented themselves in the last stages of malignant disease. At the other extreme are the private patients of Class II for the most part intelligent and in general consulting the surgeon at a much earlier stage for treatment.

There are, of course, no superficial malignancies included in these statistics.

Class I. Complete records were obtainable in 74 cases between January 1934, and September

1939. There are 6 of these patients still alive, a 5 year survival percentage of 8 (Table I).

Class II. Because of the personal records kept by the author it has been possible to collect 40 cases of cancer dating back as far as 1909. Of these 40 patients treated surgically for cancer 20 are still alive, a survival percentage of 40 plus (Table II).

TABLE II

Organ	Cases treated	Living 5 years or more
Breast	25	16*
Cervix	11	3†
Stomach	6	1‡
Colon	1	0
Ovary	1	0
Total	44	20

*The 16 cases lived 1½ to 5 years. 3 of the dead cases lived over 5 years and died from other causes.

†The 3 cases had radical hysterectomies and died without recurrence.

‡Case of subtotal gastrectomy.

General comment. The surgical treatment (radical mastectomy) of breast cancer has been the most successful in both classes as shown both in the general survival figure and in the survival figure of the special groups.

Breast

Class I, 11 cases Class II, 25 cases

Alive, 5 (45 per cent) Alive, 16 (64 per cent)

Total survival per cent of breast 58.

Total survival per cent of all cases 21.

The very poor survival rate in cancer of the cervix uteri seems to be a combination of two factors, late appearance for treatment and lack of radiation. The latter fault has been completely corrected by the recent installation, in Roper Hospital, of modern deep X-ray therapy and an adequate supply of sufficiently filtered radium. Only widespread public education concerning cancer can get patients to seek medical advice when their malignancy is in its incipency.

TABLE I

Organ	Cases treated	Living 5 years or more
Cervix	27	1*
Fundus	1	0
Breast	11	5†
Stomach	9‡	0
Mouth	6	0
Pancreas	4	0
Bladder	4§	0
Prostate	4	0
Esophagus	4	0
Miscellaneous	4	0
Total	74	6

*The only case treated by radium.

†All cases with lymph node involvement. No radiation used.

‡Exploratory laparotomy on 7. No gastrectomies.

§No radium, X-ray or electrocoagulation used.

||No radium, X-ray or surgery.

Chart 9. Five years, Group 111

lymphosarcomata lived 8 and 10 years, respectively and 3 of 28 with Hodgkin's disease lived 5, 5 and 6 years, respectively. Of 13 prostatic cancers 1 patient who had both prostatectomy and heavy irradiation died of intercurrent disease 5 years later, but among these 13 radical treatment was the exception rather than the rule (Chart 1).

A summary of this report may be seen from the first composite chart—our follow-up is 86 per cent complete for the entire 596 cases, and is curiously constant for each of the year periods. Time and effort will improve this.

Our average ratio of apparent 5 year cures is 1 in 4, dropping to 1 in 5 for the 10 year series of 166 cases.

Next to the stimulus this review of our own cases gives us to strive for better future results and greater completeness of follow-up its most suggestive feature seems to us the demonstration of the necessity in the case of the less frequent types of cancer for periodic pooling and analysis of comparably recorded data, accumulated by individuals or by large clinics along the lines already laid down by the American College of Surgeons. In that way only can series of the rarer types be secured large enough to be statistically significant.

SOME CANCER CURES¹

MONT R. REID, M.D. AND WILLIAM M. MILLAR, M.D., CINCINNATI, OHIO

From the Department of Surgery of the College of Medicine of the University of Cincinnati and of the Cincinnati General Hospital

IN this report we present two series of figures dealing with cancer. One is taken from the ward cases of the General Hospital of the City of Cincinnati and the second group has been secured from the private records of two of the senior surgeons on the staff of the College of Medicine of the University of Cincinnati.

It should be realized that when the average surgeon or radiologist enters into the field of statistics he is walking upon dangerous ground and figures of comparative methods and medical cures should always be viewed with the greatest caution. In the study of cancer mortality there are entirely too many factors that enter into the question to allow anyone to make any definite statement or to express any positive ideas on the subject. A few of these variables may be briefly mentioned.

A. One should be cautious in dealing with any case below the mean survival age, which is now considered to be about 57 years. For it should be remembered that this is the *mean* age and that below that time a "5 year cure" will become less significant the younger the individual happens to be. Statistically speaking a patient of 35, for example, has a much better expectancy than does a case of 65. This age factor, therefore, has a definite influence on a group of statistics over a wide age period and is too often forgotten by therapeutic enthusiasts.

B. No one knows how many cases of cancer exist for years without symptoms. All of us can recall individuals who have lived 10 to 20 years without operation and who have finally come to see us because of an extensive ulceration or beginning pain.

C. The position of the lesion is important. The new-growth may or may not be where the patient will soon become aware of it. Then, too, the location is important because of the operability factor that is involved.

Space will not permit any further elaboration of the other numerous difficulties involved. However, these points will tend to show that we cannot as yet view the cancer problem from a purely scientific basis for the great reason that we have no proper control of the many variables that exist. It would seem, then, that at the present time the treatment of cancer still depends to a great extent upon two personal equations: the

skill of the doctor and the intelligence of his patient. Everyone will recall cases in which he *knows* that he has helped to prolong life and that if less care had been exercised in his surgery or radiation the patient would have soon died from a metastatic growth. But he cannot *prove* this. He also realizes quite well that the earlier the individual will come to him the better is the chance for a satisfactory result.

PART I

The report which we first present is far from a pleasing one. In an effort to investigate the number of "5 year cancer cures" at the General Hospital of the city of Cincinnati we have examined the histories of 1,098 cases² diagnosed as "malignant" which were admitted to that institution during the years 1920-29.

The end results of 317 of these are not known to us. There is no record to be found in either—(a) the death records of the city's Bureau of Vital Statistics for a 4 year period following their admission to the hospital for a malignant condition, or (b) in the city directory for 1933-34. (Where an individual or individuals with the same name but different address was found in this book, follow up letters were forwarded to them in an effort to secure definite information concerning these missing cases.)

The picture set forth in Tables I and II is dreiful. We offer no "alibis" but these results can be explained in part as due to certain conditions peculiar to a City Charity Hospital.

1. The hospital receives its patients from the lower social classes.

2. Individuals of this stratum tend to put off treatment of any condition until the last possible moment.

3. Hopeless cases are sent into the hospital by the doctors and by families when treatment has become merely a question of proper bed care and opiate therapy. This statement is borne out when it is noted that 463 out of 1,098 died in the hospital.

4. There was a lack of "proper follow up" in the first 9 years of this period. Three hundred and seventeen "unknown" is entirely too great a

²It is possible that all of the cases of cancer admitted to the hospital in that period are not included in the number because of an inadequate filing system for the first few years of that interval.

¹Presented in the symposium, Cancer Is Curable, before the Clinical Congress of the American College of Surgeons, Boston, October 17, 1934.

number. An attempt has been made to remedy this by establishing a tumor clinic at the General Hospital Dispensary (1930). This is now in charge of one doctor who is aided by 3 visiting surgeons, Public Health Federation nurses and a part time secretary.

PART 2

The private records of the senior surgeons of the surgical staff of the Department of the University of Cincinnati (Drs. M. R. Reid and B. N. Carter) were then examined for cases in which operations had been done in Cincinnati prior to 1930.

The actual distribution of cases is shown in Table IV.

Comment. Any comparison which one desires to make with these two groups must be done with the utmost caution. In the first place only two classifications of the private series are large enough to permit an attempt at any evaluation. These are the "stomach" and the "breast" cases. But it will be seen from Tables V and VI that the reduction of them to a percentage basis in order to compare them will allow only the former to be

analyzed and even then the number is too small for any satisfactory conclusions.

SUMMARY

The cases of "5 year cures" which we present are taken from two classifications. One group is from a large series of 789 and has been secured from the records of a large city charity hospital; the other is a small number of 24 and has been taken from the private cases of two general surgeons. We have no great time to elaborate on them. It would seem, however, that one of the chief things now necessary to do and to emphasize is getting the public educated and interested enough in cancer to allow the physician a better chance to be of permanent benefit to his patient. In other words, individuals with cancer should be

TABLE IV—DISTRIBUTION

Cancer location	Total	Living	Dead
Breast	6	6	3
Stomach	3		
Thyroid			
Rectum			
Esophagus—Carcinoma ("large hotel")			
Cervix			
Melanoma			3
Cholangitis			6
Retroposterior carcinoma			3
Total	24	11	3

*Small lesions are not included in this list. They would, of course, increase the living group.

TABLE III—PRIVATE CASES

Total cases of known malignancy about whom information is available	Per cent (see Table I)
Total cases of these malignancies which are known to have lived 5 years or more	4
Total cases which are known to have died (other 5 years after operation)	44
	3 34

Comments. One of the cases which is listed as "dead" was killed in an accident. On the other hand, of the cases recorded as having lived for over 5 years died in the fifth year following her operation. None of the others are at present living and well.

TABLE V

Total number of actual cases considered—breast	Actual number of breast cases	Percentage of actual total number	Actual number of stomach cases	Percentage of total number
Cincinnati General Hospital series 786	84	10	84	0
"Private" series 24	0	37	5	80

seen in the operable stage and not at the very end. The ordinary charity patient with this disease is seen entirely too late. In our series 59 per cent died in the hospital from malignancy and 40 per cent were dead in 4 years after they had left the hospital. It is true that therapy was instituted in many cases in the desperate hope that the unusual and the miraculous would happen. It did not. There are only 8 people with proved cancer of this group who have lived for 5 years. Contrast this with the private cases. Here we find 11 out of 24 were alive for 5 or more years after their operation.

It can be seen at once that this report may be considered from two diametrically opposite viewpoints. The pessimists will point gloomily at the 99 per cent the optimists will comment on the results of the private group. We are inclined to take our places with the latter, for while it is true

TABLE VI

Stomach cases	Total number with results known	Alive	Percent age	Dead	Percent age
Cincinnati General Hospital series	84	1	06	153	00 04
Private series	5	1	20	4	80

that these two series cannot be compared scientifically and biometrically, for the reasons stated, nevertheless these results tend to show what has been known for years—that cancer can be checked in a very considerable percentage of cases if it is treated early enough.

Furthermore it would seem that the personal equation or rather two personal equations, enter strongly into the whole question. One is the skill of the surgeon, the X-ray man, or the radiologist, the other is the early co-operation of the patient. The average surgeon and radiologist can generally do a good job nowadays if he has a fair chance. It is now up to the patient to do his part, and it is to this end that the public should be educated.

CONCLUSIONS

1. Caution is advised against any pseudo-scientific attempts to evaluate statistics on cancer.
2. Nineteen proved cancer cases which lived 5 or more years following operation are presented.

FIVE YEAR CURES OF CANCER IN DETROIT HOSPITALS¹

HARRY C. SALTZSTEIN, M.D., F.A.C.S., DETROIT, MICHIGAN

IN 1927 the Department of Health of Detroit established a cancer division. It functioned (in co-operation with the Wayne County Medical Society) as a registry for the cancer cases treated in all the Detroit hospitals.¹ The depression and other causes have curtailed the plans and the work, but the attempt has been made to follow the cases collected in 1927, 1928, and 1929 for 5 years.

Figures collected in this manner from several different hospitals, with varying degrees of interest and changing organizations, are not as accurate as those obtained under the auspices of one hospital and staff. No case was included unless the pathological diagnosis was recorded but these were not rechecked. (Certain stomach cases, where X-ray and clinical examination were conclusive were accepted.)

Now under the auspices of the Cancer Committee of the Wayne County Medical Society, Dr. O. A. Brown, chairman. This report is published with their approval.

However, for the years and body organs stated the attempt was made to include all of the cases treated in the 13 hospitals. Several cancers in other body regions have been cured 5 years, but the number is too small and the total number of cases treated not known accurately enough to be of value. The table, therefore, is a fair exhibit of the work from all the general hospitals of a large city. (There were no special cancer institutions or concentration of cases.)

The accompanying table shows that in average circumstances—

1. Many breast, cervix and fundus cases are cured regularly. Cures of breast cancer approach the proportion obtained in the carefully compiled series from large institutions.

2. The 5 year accomplishment in stomach cancer is very small. A few rectum and colon cancers are cured 5 years.

3. A few sarcomata are cured 5 years.

Presented at the symposium, Cancer is Curable, before the Clinical Congress of the American College of Surgeons, Boston, October 27, 1934.

FIVE YEAR CANCER CURES AT ST LUKE'S HOSPITAL¹

FRANCIS CARTER WOOD M.D., AND BENJAMIN RICE SHORE, M.D. F.A.C.S. NEW YORK, NEW YORK

THE 333 cases which we wish to report represent the known 5 year survivals of patients whose cancers were histologically verified and who were treated in the surgical wards and radiotherapeutic department at St. Luke's Hospital, New York City. Some 110 private patients are included whose histories have been supplied from the personal records of several of the surgeons. All these patients, with a few exceptions, were treated during the 10 year period from 1919, when our follow up department was begun, to 1929. The actual number of 5 year survivals is much greater because many favorable cases have been lost to our follow up department. Patients with recurrences perhaps leading to death, are much more easily followed in a large city than are those who remain well, or who change residence or secure employment in other localities. The ever present suspicious attitude of many clinic patients toward investigators adds to the difficulty of tracing patients in a large community. In New York City great tact and persistence on the part of the surgeons and follow up nurses are necessary if patients are to be followed for a period of years. We have found that much use can be made of the radiotherapeutic department in this respect. Patients who sometimes return reluctantly, or not at all, to the regular follow up clinics for examination will gladly come to the radiotherapeutic clinic for postoperative treatments. It is easy to gauge the latter to the needs of individual patients and many can be persuaded to return for treatments and observation over a long period of time.

A statistical study of cancer therapy at St. Luke's Hospital is not included in the present report. Such a study of 1,000 consecutive patients with cancer admitted to the hospital from July 1, 1923, to January 1, 1927, was made and published several years ago. At that time it was found that only 32 per cent of the patients applying for admission to the hospital had operable growths and known 5 year cures were obtained in 30 per cent of the operable cases, or only 7.8 per cent of the entire number. It is reasonable to suppose that better end-results in cancer therapy depend more on securing patients in the earlier stages of the disease than upon greater refinements in surgical or radiation technique. For the attainment of better results, education—first of the medical profession and second of the laity—appears to be our greatest need today.

The operations on the patients here recorded were performed in St. Luke's Hospital, and histological study of the tumor is available in each case. The slides are on file and many of them have been reviewed for this report. Tumors of questionable malignancy, such as serous papillary cystadenomata of the ovaries and cellular adenomata of the thyroid gland, and patients in whom the duration of life is not accurately known, have been excluded.

Table I shows the sites and character of the growths.

Instead of discussing further these purely statistical results, which differ in no way from those obtained in other hospitals whose surgeons and radiologists are treating cancer patients intelligently and conscientiously, we have selected a few unusual and interesting cases to review.

The first patient had a Grade I squamous cell epithelioma (Fig. 1) of the tongue which was cut into for a biopsy specimen, the wound sutured and a month's time allowed to elapse before the remainder of the lesion was removed. A local excision of the primary growth and a dissection of the right submaxillary triangle were done and the patient has remained well for 19 years.

Fig. 1. Grade I squamous cell epithelioma of the tongue. Patient well 19 years after local excision and dissection of one submaxillary triangle.

¹Presented in the symposium, Cancer Is Curable, before the Clinical Congress of the American College of Surgeons, Boston, October 17, 1934.

Fig 2 Metastatic melanoma in inguinal nodes from primary tumor on sole of foot

The second patient was operated on by Dr F S Mathews for a malignant hypernephroma of the left kidney. This was a huge growth measuring 21 by 13 by 8 centimeters and the prognosis at the time appeared extremely unfavorable. This patient is now entirely well and free of symptoms 7 years after the nephrectomy.

Fig 4 Spindle cell sarcoma of the toe. Patient well 20 years after amputation of the toe only

Fig 5. Advanced carcinoma of the breast involving the axillary lymph nodes, fat and fascia. Patient died 7 years after radical mastectomy (Courtesy of Dr John Douglas)

A pigmented nevus on the sole of the foot of the third patient was excised locally by Dr William A Downes. Several months later a large mass of coal black lymph nodes containing metastatic melanoma was removed from the inguinal region (Fig 2) and 5 months after this a nodule of metastatic tumor (Fig 3) was removed from the left lumbar region. Since that time there has been no evidence of further dissemination of the growth and the patient has remained well for 15 years.

The tumor in the fourth case was a spindle cell sarcoma of the great toe of an adult patient. A biopsy specimen was taken in the clinic and one week later the toe was amputated. The diagnosis of spindle cell sarcoma was made from histological study of the specimens (Fig 4). This patient has remained well for 20 years.

The last patients which we wish to present are 2 of 6 cases of apparently hopelessly advanced carcinomata of the breast which have survived for over 5 years after what at the time were

Fig 6. Advanced carcinoma originating in the axillary tail of the breast. Axillary nodes extensively involved. Patient well 8 years after radical mastectomy (Courtesy of Dr M E. Smith)

thought to be purely palliative radical mastectomies. In both of these instances the primary tumors were large and metastatic cancer was found not only in the axillary lymph nodes but also involving the axillary fat and fascia (Figs. 5 and 6)

These cases have been reviewed to show that neither the histological nor clinical grading of tumors can be relied upon for the correct prognosis in the individual case and that to obtain the best results in cancer therapy all growths no matter how advanced, must be treated in a thorough and intelligent manner. The biology of the patient and the biology of the tumor which he harbors are the two great unknowns present in every case of cancer.

CANCER OF THE BREAST IS CURABLE¹

THOMAS A. SHALLOW, M.D., F.A.C.S., PHILADELPHIA, PENNSYLVANIA

WHEN one considers the statistics of the past 30 years, one must admit that cancer of the breast is a curable condition. This conclusion is reached after a careful summing up of the reported cases of malignancy of the breast in which the patients have remained well beyond the 10 year period, even when they came to the operating table under the most adverse circumstances. One would naturally conclude that, in the average case which comes to the operating table, the growth has existed from between 6 and 12 months, and in 75 per cent of the cases metastasis has involved the adjacent lymphatics, while in over 67 per cent of the cases the skin is adherent to the tumor. In other words, a well advanced cancer is the rule rather than the exception when the surgeon first sees it.

The operation for carcinoma of the breast is not attended with any great shock, nor is any vital structure destroyed, yet, because of its anatomical situation, perfect exposure is possible not only of the involved breast, but also of the adjacent muscles, the fascia and the lymphatics.

Is surgery alone sufficient for the cure of cancer? In this series of cases, surgery has been fortified by postoperative X-ray treatment. We have seen beneficial results in 2 cases, postoperatively where the carcinoma had spread to the ribs in one patient and to the spine in the other. In both of these patients, following intensive X-ray treatments, the metastatic areas disappeared and were replaced by what apparently was normal bone structure. In one case the patient is still living 7 years after the beginning of the X-ray therapy and the other 12 years after her operation.

We have noted further that in those patients in whom postoperative treatments were faithfully carried out, local recurrences and distant recurrences were the exception. But, on the contrary, in those individuals who did not report for postoperative X-ray treatment, local recurrences were more common.

The cure of cancer must depend upon its early recognition. This is only possible through intensive propaganda among female patients and the medical practitioners. It has been stated previously that carcinoma is seldom recognized before the sixth month and usually not before the twelfth. This golden period of formation, localizing growth, limited involvement without metas-

tasis, is the ideal time for surgical intervention. Then carcinoma is curable in certainly 70 per cent of the cases.

We cannot blame the medical man for not making an early diagnosis of carcinoma of the breast, particularly when carcinoma is associated with chronic interstitial mastitis. We are told by good authority that a chronic mastitis is very frequently a forerunner of cancer. This statement is disputed by others of equally good authority. What is the medical man to believe? We should teach him that carcinoma of the breast can and does originate in breasts in which there is chronic mastitis. In this series of 100 cases, 32 patients had definite chronic mastitis and the cancer was not recognized because they were told that cancer was never painful until the end. Most of them had consulted physicians and were given some form of glandular therapy with the hope that a cure would be effected.

We have been teaching for so long the characteristic phenomena associated with the well advanced carcinoma that very frequently mistakes are made. In 3 cases that I recall distinctly at this time, younger surgeons in one of the hospitals with which I am associated removed small tumors from the breasts as finishing touches to abdominal operations, believing that they were dealing with benign growths. The pathological reports returned in 2 weeks after the removal of these growths showed cancer in every case. When questioned about his work the surgeon's answer was, "I thought it was an area of mastitis." Had a frozen section been made, the true nature of the pathology would have been disclosed and a radical operation would have given us 3 excellent cases for cure.

Tumors of the breast should not be the tail of a kite, such as these 3 cases were, but, on the contrary they should be considered of the utmost importance from the standpoint of the patient and the preparation of the surgeon for the procedure.

Within recent years the differential diagnosis between cysts and solid tumors has been made possible by Cutler's method of transillumination of the breast. This is indeed a help in separating some of the benign cystic tumors from malignant ones. X-ray studies of the breast have added, even more than transillumination, to early diagnosis. Both of these methods, however should be used to their fullest extent. If the aver-

age case were looked upon as a potential malignancy, it would lead to earlier operative intervention and a higher percentage of cures. One often wonders why some of our patients with cancer of the breast live as long as they do since they are very frequently far advanced before they come to the operating surgeon.

The prognosis and treatment of cancer of the breast will be improved when (a) the medical man loses the time worn expression 'If it doesn't bother you let it alone', (b) the diagnosis of carcinoma is made before the skin is adherent

and before the adjacent lymphatic glands are involved.

Improvement in prognosis and treatment can be accomplished not only clinically, but by the aid of transillumination and X ray examination, when the medical man realizes that it is not uncommon for carcinoma to develop in a breast in which there is chronic mastitis. Thirty two patients out of the series of 100 reported here had had mastitis.

Moreover, progress will occur when we realize that in those patients in whom there is a discharge either of blood or of clear fluid from the nipple the likelihood of carcinoma is about 40 per cent.

FIVE YEAR CURES OF CANCER OF THE BREAST AND OF MELANOMA¹

A. C. SCOTT, JR., M.D. F.A.C.S., TEMPLE, TEXAS

WE believe that 95 out of every 100 patients with cancer of the breast can be cured today. This statement is based on our experience during the past 15 years in treating 3,167 patients with various types of cancer, and an intensive follow up study of 236 breast cancer cases treated by hot knife surgical removal.

The only conditions necessary to obtain this high percentage of cures are first, treatment while the tumor is limited within the breast, and second, complete removal with the hot loop-knife.

The ratio of curability of cancer is dependent today upon three known factors: the time after onset when the patient seeks treatment, the curative agent employed, and the degree of malignancy. The first two factors are more or less controllable by the medical profession.

It has often been stated in recent years by excellent authorities that the only hope at present for increasing the percentage of cures lies in educating the public to seek treatment earlier, and that very little can be expected from improvement of surgical technique. The impression has been given and is being broadcast that surgery has reached its limit as a curative agent. We disagree with this view.

We are convinced that hot knife surgical removal offers a 10 to 20 per cent better chance of cure of cancer of the breast, even though metastases to the axilla may have occurred, than the use of any other curative agent known.

In 1926 I presented a study of 1,000 cases of various types of cancer treated by this method and on numerous occasions Dr. A. C. Scott, Sr.

has described the technique of the hot loop-knife operation. In the series of 3167 cancers treated in our clinic between the years 1918-1933 inclusive, it was the principal remedial agent employed in 86 per cent of the cases. I am not prepared at this time to report the 5 year cures of the entire series, but I will briefly report a small 5 year group of totally different types of cancer treated by this method.

Cancer of the breast. The first radical breast amputation and gland dissection performed exclusively with the hot loop-knife was done in our clinic in 1920 and between that time and the end of 1933 236 similar operations were performed for cancer of the breast. Of this group only 124 patients have been operated on 5 years or longer and 58 patients of the entire 5 year group were alive and well at the end of this period.

In this group of 124 patients, 16 had received various types of surgical interference elsewhere before entry and 1 had received extensive X ray therapy. 107 patients had their primary treatment in our clinic.

In the group receiving primary treatment in our clinic 18 operations were considered palliative because of one or more of the following conditions: chest wall attachment, diffuse skin involvement, fixation of axillary metastasis, indurated cervical glands or probable distant metastases as indicated by X ray changes of lung, pleura, or bone.

Eighty nine patients were considered operable and potentially curable, irrespective of whether or not they had palpable axillary metastases. Eighty four of this operable group have been traced. Fifty two patients or 61.9 per cent were alive and well 5 years or longer.

Fifty four patients of the operable group had proved axillary gland metastasis. Fifty of these were traced. 24 died of cancer, 4 died of intercurrent disease or other causes. Twenty two patients or 41 per cent of this group of traced patients were well 5 years later. If the patients who died

of intercurrent disease are eliminated, 22 of the 46 traced patients, or 47.8 per cent, lived 5 years.

Thirty-five patients of the operable group had no pathological evidence of regional gland metastasis. Thirty four of these were traced. 1 died of cancer, 3 died of other known causes. Thirty patients or 88.2 per cent of this group of traced patients were well 5 years. If the patients who died of intercurrent disease are eliminated, 30 of the 31 traced patients, or 96. per cent were well 5 years later.

Malignant melanoma. Malignant melanoma, variously termed melanosarcoma, melano-epithelioma, non-melanotic melano-epithelioma, neurocarcinoma, etc., is generally conceded to be one of the most malignant of all types of cancer and almost inevitably fatal. We have operated with the hot-loop-knife on 53 patients with this condition in an attempt to cure, and have traced 46 of these. Twenty nine of the traced patients had been operated on 5 years or longer prior to 1934. Although this is a very small series, our results in treating this most malignant and hopeless type of cancer have so startled us that I think they are worthy of presentation.

Of the 29 patients, 11 or 37.9 per cent were alive and well 5 years or longer. Ten of the 29 had regional gland dissections with demonstrable metastasis and 3 patients, or 30 per cent of those with metastases were alive and well 5 years. Of the 11 five year cures, 4 had Grade II, 6 had Grade III, and 1 had Grade IV malignant melanoma.

SUMMARY

A greater number of patients are being cured of cancer today than ever before, alive by radiologists and surgeons, but we are convinced that a still greater percentage of all surface and accessible subsurface cancers can be cured by the more general use of the hot loop-knife for complete removal.

FIVE YEAR CURES OF CANCER OF THE STOMACH¹

RICHARD LEWISOHN M.D. F.A.C.S., AND SIGMUND MAGE M.D. F.A.C.S., NEW YORK, NEW YORK
From the Surgical Service Mount Sinai Hospital

CANCER of the stomach represents a fatal disease unless attacked surgically. In contradistinction to cancerous growths in other locations (mouth skin uterus), which can be cured by radiotherapy in a large percentage of cases, surgery represents the only possible curative method for gastric carcinoma.

In view of the absolute hopelessness of this disease unless removed by operation, we agree with Dr. A. A. Berg who was in charge of this service until recently that no attempt should be made to keep the operative mortality for gastric carcinoma at a low level by refusing to subject patients to radical resection who are at the borderline of operability.

The high operative mortality of cancer of the stomach on this service (33 per cent) is undoubtedly due to many daring attempts to remove the carcinoma even in extensive growths with local metastasis, instead of classifying the patients as definitely inoperable.

Six hundred and forty seven patients with carcinoma of the stomach were admitted to Mount Sinai Hospital between January 1, 1922, and January 1, 1932. Two hundred and sixty five

were explored, in the rest, either the condition was found definitely inoperable on account of metastasis in other organs, or operation was refused.

Ninety three radical resections were performed, the remaining 172 cases (65 per cent) were inoperable. The high incidence of inoperability encountered even on this service which tried to extend the limits of operation as much as possible re-emphasizes the urgent need for early investigation of indefinite gastric complaints by roentgenography.

We were able to maintain a complete follow up on 88 per cent of the cases operated upon between the years 1922 and 1931 inclusive. Our follow up records on cancer of the stomach previous to 1922 are very incomplete.

We know of 10 cases of carcinoma of the stomach which have been well for 5 years or more following gastric resection (see table). In 3 of these cases the operation was performed more than 10 years ago.

Only 2 of these patients were below 50 years of age at the time of the operation. It is generally conceded that as a rule cancer in persons under

10	930	Chas. K.	305456	33	18 years	Negative	Achsner	Adenocarcinoma with lymph node involvement probably on ulcer basis		3 years

50 is more malignant and gives a less favorable chance for radical cure than in persons past the fifth decade.

Seven patients were males and 3 were females.

Gastric symptoms had been present for a year or more in 6 cases. It is often stated, even by experienced practitioners, that abdominal exploration should not be performed if symptoms have persisted over a fairly long period. In this series 6 cases were amenable to radical surgery in spite of the fact that in 3 cases symptoms had been present for 1 year and in 4 cases for a number of years. In those cases in which the symptoms had persisted for 5, 6, 10 and 18 years respectively, the carcinoma probably developed on an old gastric ulcer.

In 7 cases no mass was palpable. 3 cases (30 per cent) could be subjected to gastric resection, in spite of the pre-operative palpatory findings of a hard tumor in the upper abdomen. The dictum that palpable masses definitely indicate inoperability is as much a fallacy as the statement that

absence of a palpable mass excludes a malignancy of the stomach.

In 9 cases the Billroth II method was used and in 1 case a Billroth I. The Billroth II method is preferable in carcinoma of the stomach, as it facilitates a wide resection of the new-growth.

It is of great interest to note that the microscopic examination showed lymph node involvement in 4 of these cases. We have always maintained that local metastasis is no contra indication to radical operation.

Thus in our material about 20 per cent of the resected cases of gastric carcinoma surviving the operation were still perfectly well after 5 years or more. Gastric carcinoma does not offer a hopeless prognosis and under certain conditions has about the same chance for a permanent cure as cancer in some other parts of the body.

For this reason partial or subtotal gastrectomy should be attempted even in extensive involvement of the stomach as the only possible chance for a permanent cure.

CANCER IS CURABLE¹

FREDERICK C. HOLDEN M.D. F.A.C.S., New York, New York

SINCE cancer of the cervix still remains so formidable a foe, we must marshal our most powerful forces to continue fight ing it.

Our program is threefold

1 Further research in the etiology, diagnosis, and treatment.

2 Prevention or cure of the pathological condition which predisposes to cancer

3 Education of the profession and laity to make full use of the knowledge and facilities already available to them.

I wish to stress the two last points. Prevention of disease is the ideal toward which we strive. The most important measure in the prevention of cancer of the cervix is the repair of the damages of childbirth either immediately after delivery or preferably 4 to 8 weeks later. In many instances cervical injury can be cleared up by proper use of the nasal tip cautery at the 6 weeks' postnatal visit. R. L. Dickinson and the author have for many years used the nasal tip cautery for the cure of lacerated and eroded cervixes, and have never seen carcinoma develop in a cervix so treated by them. The laity especially must be educated to the fact that postnatal care of the cervix is the most important measure for prevent ing cancer of the cervix.

We do not approve of routine total hysterect omies and think this operation because of its increased mortality and morbidity should be reserved for those cases in which it is definitely indicated. However there is a small percentage of cases wherein cancer develops in the retained cervix after a supravaginal hysterectomy. This percentage could be almost entirely eliminated if the entire endocervical canal and eroded areas are thoroughly cauterized 4 to 6 weeks after operation.

Another important step in the educational program is to dispel the almost universal belief that a diagnosis of cancer carries with it certain death. Cancer is curable if the diagnosis is made early enough, therefore we must exert all our energies to reach the cancer patient in the initial stage. This is not as simple as it sounds, for although many educational campaigns have been carried out to teach the public what the early symptoms of cancer may be still, early symptoms do not mean an early stage of the disease. Cancer in its initial stage has no symptoms, and herein lies its

greatest danger. For this reason, in order to bring the cancer patient to the doctor early, I strongly advocate yearly general examinations, including a careful pelvic examination for every woman. Too often many symptoms are casually dismissed by the patient as 'Oh! It's the change of life,' and so, during this period, these examinations should be carried out every 6 months.

The inherent danger of vaginal discharge, irregular vaginal bleeding, postcoital and postmenopausal bleeding, or abdominal mass, should be brought to the consciousness of every woman, but again I stress the point that only by routine pelvic examinations will early cancer of the cervix

be detected and the probability of cure greatly increased thereby

In reporting our cancer series at Bellevue Hospital, I am presenting the darkest side of the picture, because of the economic status of our patients. This factor in itself bears out the above points. The incidence of cancer of the cervix is much higher in the poorer classes than in the well-to-do, since the early initial symptoms which are given immediate attention by the well-to-do are either overlooked or disregarded by poor overworked women. To illustrate, we have never received a Group I case for treatment. Also in this class of patients we are greatly handicapped by lack of co-operation in the follow-up and proper after-care. Even with this most discouraging group we have some cures to report. With a higher economic group the cures would be greatly increased, showing what education and early care can accomplish.

At Bellevue Hospital for the past 9 years, irradiation has been used exclusively for cancer of the cervix. All cases were biopsied and classi-

fied pathologically. In our experience the pathological findings have not helped us to prognosticate the course of the disease but they have aided in planning the dosage of radium to be used in any given case. Fistulae did not develop in any of these cases.

SUMMARY

Healing the injured cervix by proper postnatal care, is the most important prophylactic measure for cancer of the cervix.

We advise routine thorough cauterization of the endocervical canal and of the retained cervix following supravaginal hysterectomy.

Early cancer of the cervix gives no symptoms. For this reason, periodic general pelvic examinations should be carefully done. By this means it is possible to detect benign cervical lesions, which can then be treated, or to discover an early cancer if present.

The public should be educated as to what symptoms require immediate attention.

There is no cancer age.

Cancer is curable if treated early and properly.

CANCER OF THE CERVIX.¹

C. JEFF MILLER, M.D. F.A.C.S. NEW ORLEANS, LOUISIANA

THE intent of this symposium, as I understand it, is to present incontrovertible proof of the curability of cancer by collecting a large series of cases that have been treated and have remained well and free from active malignancy for more than 5 years. The report must necessarily be brief and for that reason I have not arranged a statistical study but will simply present the results, as obtained by letters to patients and physicians, in a series of private cases treated prior to 1929. The report is limited to private records because it was impossible to make necessary inquiries and checks of the large amount of material that passed through the wards and clinics of the busy services under my direction in two public institutions. Even the collection of data from private patients proves a tedious task, for as usual, a great many ignored written requests.

The oldest living case in my series was first treated in 1908. I can definitely report that 42 patients treated between 1908 and 1929 for cancer of the cervix have reported personally or through their physicians, that they are well. Eight of

these cases were treated by radical hysterectomy between the years 1908 and 1915. After 1915 only 3 radical hysterectomies were performed, as I had become convinced that too much confusion existed as to the clinical classification of early borderline and advanced cervical cancer that the primary mortality of the correctly performed radical hysterectomy was too high, and that over 70 per cent of cases applying for treatment had to be thrown into the discard as unsuitable for anything more than palliative measures. After 1915 radium was used in all cases early and advanced. Of these treated between 1914 and 1929, 34 recently reported that they have remained well. Twelve of this number had X-ray treatment in addition to radium. The cases subjected to combined irradiation were treated between 1922 and 1929 and as a rule were more advanced. The results in this series have convinced me of the advantages of this method. In addition to irradiation, the electrocautery was freely used in removing everting, crumbling cervixes, and Norris' suggestion for separating raising and packing away the bladder with gauze during the irradiation.

tion (to prevent subsequent complications), was occasionally done. Most of the cases received within one week from 3,000 to 4,000 milligram hours, and subsequent radium exposures were given only for definite reasons. Repeated treatments every 60 or 90 days, as advocated by some clinicians too often result in fistulae and other complications to warrant the adoption of this method as routine.

My report is brief but I wish to emphasize one or two features of the cancer problem that are equally as important as presenting a series of cured cases. May I speak briefly of the necessity of creating a different attitude on the part of the physician who is brought in contact with patients *who seem to indicate the possibility of cancer?* If cancer is to be detected earlier, this must not be accomplished merely by the ability to recognize cancer but by appreciating as well the relation of other diseases to malignancy. Proper prophylaxis of cancer will yield greater salvage of lives than can be obtained by our present available methods of treatment. Further education of the profession is necessary. Frankly, since we believe that cancer is originally a local process, are we consistent in teaching that the early signs of cancer of the cervix are bleeding, discharge, and pain? Are we not summarizing as early signs of malignancy the indications of impending death rather than the symptoms of cancer? A new clinical entity must be described to replace the present stereotyped syndrome.

'Cancer does not have a life history of a few months or a year, but is a disease that usually takes several years to run its full course' (Mc Carthy). The word *early*, which we use so freely, must be more clearly defined. Many of the really early cases of cancer of the cervix are found by accident when routine microscopic examination

of cervical tissues removed in performing plastic operations is done. Such routine study should be required in all hospitals, as properly performed biopsies are not done as often as their importance justifies. Biopsy should be the rule not only in suspected cancer, but in apparently simple chronic inflammatory lesions and obstetrical injuries.

The physician must be kept cancer-conscious. For this the Schiller test is excellent. While not a positive test for cancer, it prompts the routine search for malignancy, and materially assists in differentiating other lesions not recognizable by ordinary inspection. It is especially useful in designating tissues to be removed for microscopic study. The same can be said in regard to the colposcope in the diagnosis of suspicious lesions.

It is certainly permissible to question whether the lay education has been as thorough as it might have been. It has been carried far enough to prove its vast possibilities, yet in our large charity hospitals over 20 per cent of cancer patients are dying without having had either surgery or irradiation. The lay press and the radio are co-operative, but we are overlooking the fundamentals of publicity, viz., repetition and perseverance. The agencies of publicity should be persistently utilized, not to relate the horrors of cancer, nor to emphasize the number who die from it annually but to instill hope, and to disseminate knowledge concerning the value of routine health examinations, not, as Lord Moynehan says, 'by scaring people to death but scaring them into life.'

These are commonplace comments but they are truths worth repeating. 'Commonplace after all is exactly what contains the truth that is indispensable' (John Morley)

CANCER OF THE BREAST¹

W T COUGHLIN, M D, F.A.C.S. St. Louis, Missouri

IN the city of St. Louis, 10 or 11 persons out of every 100,000 die each year of cancer of the breast. Surgeons' statistics are usually compiled from the cases in the large clinics. Most of us present are more interested in what happens in our individual practices. Every surgeon keeps personal records of his cases, uses the follow up and from time to time takes stock and knows just how he stands. It isn't always pleasant but it is highly desirable.

Up to 1939 the author treated 204 private patients (and took care of them himself) under the diagnosis of breast tumor. In these the presence of cancer was proved microscopically 63 times (All of these 63 were private patients and all were white females). Therefore, the benign lesions were 41. Roughly speaking 2 out of every 5 were benign and 3 out of every 5 were cancer. This is a high percentage of benign tumors. Thirty years ago we taught that at least 4 out of every 5 lumps in a woman's breast were cancer. This was considered a conservative estimate. The difference is due to the propaganda for early diagnosis. Through our propaganda, at last the laity is beginning to know this truth about cancer of the breast (as through the long years the surgeons have taught them of appendicitis) namely, that in early operation lies the best hope of cure, and that, in fact, no other treatment up to the present in any way approaches in its results those obtained by early and efficient operation. When all physicians believe this truth—that any lump must be removed and examined microscopically in order to be sure that it is *not* cancer—the laity will soon learn it.

We have 63 cases for study. Of the 63 coming to operation there were still living at the end of 5 years, 29 patients. Six of the 63 had died in the hospital. Twenty-two of the 63 died of cancer within 5 years—11 within 1 year, 8 within 2 years, 1 within 3 years, and 4 within 4 years. Two are positively known to have died of other causes within 3 years—1 of pneumonia and 1 of an acute heart attack. Four could not be traced.

Our total number of cases living 5 years after operation was 29, or 46 per cent. Of these 29, 4 died later of metastatic carcinoma, 1 patient being free of any recurrence for 8 years and then dying of cancer of the fourth lumbar vertebra, proved at autopsy to be breast carcinoma, another one, having had a scirrhous cancer with implants

tion in the axillary glands, lived free from recurrence for 8 years and then died of cancer of the uterus, another lived free of recurrence and then died 6 years after operation with symptoms of spinal cord tumor—most likely carcinoma of the vertebrae, another died 5½ years after operation of metastatic cancer of lungs and bones. Of the 29, 1 lived free of symptoms for 10 years and then came with a recurrent nodule in the scar, another comes 6 years after operation with destruction of the twelfth dorsal vertebra.

Of those who died early, the average pre-operative duration of the disease was 19 months. Of those who lived 5 years or longer, it was 23 months. Of the 29 who lived 5 years or longer, 5 were known to have had cancer in the glands. Of the 22 who died early, 16 were known to have had cancer in the glands of the axilla or neck. Of the 63 proved cases of cancer, 29 had nursed babies. In the 29 five year cures, 23 had nursed babies. Of the 22 who died early, 11 had nursed babies.

With regard to heredity, the statistics do not mean much. People deny cancer in the family just as they deny insanity, so that the statements of the patient in the negative cannot be accepted without question. There were only 8 of the 63 patients who acknowledged cancer in the immediate family—father, mother, brother or sister. Of these, 7 lived 5 years and the other one could not be traced.

Of the 63 cases, there were 31 involving the right breast, 29 involving the left breast and 3 involving both breasts. Of the 29 five year cures, 11 involved the right breast, 15 the left breast and 3 involved both breasts. Of the 22 early deaths, 15 were of the right breast and 7 were of the left.

At the present time the exact status of chronic cystic mastitis is very much discussed. In our series of 204, that diagnosis was made altogether 23 times, and 9 times out of these 23 it was associated with cancer of the breast. One case in which frozen section diagnosis was questionable, and in which breast and lower glands were removed, after 6 years has developed a destructive process in the twelfth dorsal vertebra and is still living. Another one in whom the diagnosis "chronic cystic mastitis" was returned without question and in whom a similar operation was done, returned the next year with a nodule in the

breast region which was pronounced by the same pathologist "scirrhous carcinoma of the breast." Nine out of 23 cases of chronic cystic mastitis had microscopically proved carcinoma.

There are 8 different cell types named. There is no unanimity among the pathologists with regard to terminology. Of the 29 who lived 5 years or longer—

- 9 were called adenocarcinoma
- 8 were called scirrhous carcinoma
- 5 were called carcinoma simplex

- 4 were called medullary carcinoma
- 1 was called colloid carcinoma
- 1 was called duct carcinoma
- 1 the type was not mentioned.

Of the 22 who died early—

- 7 were called scirrhous carcinoma
- 4 were called medullary carcinoma
- 4 were called carcinoma simplex
- 2 were called adenocarcinoma
- 1 was called basal cell type carcinoma
- 1 was called spheroidal cell carcinoma
- 1 was called sarcoma round and spindle cell
- 2 the type was not mentioned.

CANCER OF THE BREAST IS CURABLE¹

HUBERT A. ROYSTER, M.D., F.A.C.S. RALEIGH, NORTH CAROLINA

CANCER is a symptomless disease. There are no pathognomonic signs of its presence in any organ or tissue. It may exist in the internal organs for a comparatively long time without a disturbance of function or a suspicion of its presence. In its late hopeless stages cancer of any part of the body exhibits pain, ulceration, discharge and cachexia, but these are not symptoms of cancer; they are signs of impending death.

The female breast should be one of the locations in which cancer is recognized early, for the breast is exposed to observation both of patient and physician. Unfortunately the woman frequently fails to notice changes in the contour of the breast and, as pain is virtually never felt in the early stages of malignant disease, her attention is seldom called to the occurrence of a tumor of this type until it is far advanced. On the contrary, early pain is present in tumors which are benign, and these are recognized much more promptly. Actually I believe that, thanks to wide spread publicity and educational efforts, we are observing as many benign as malignant growths of the female breast, if not more, in the past 10 years. This is real progress. All our experience and all our diagnostic judgment applied to the decision as to whether a given tumor of the breast is benign or malignant, can be laid aside in the face of one issue—the presence of any growth in the breast is the reason for its removal. Women generally must be taught a safe slogan: an empty house is better than a poor tenant—remove that lump.

These preliminary observations point the way to two facts upon which the cure of cancer of the breast depends: (1) securing the patient before metastasis has taken place and (2) thorough surgical removal of all involved tissues. The question of employing radiation in any form, either before or after operation, is of importance but radiation should be considered only as an aid in the cases suitable for operative interference. Personally I have depended upon postoperative in preference to pre-operative radiation. This procedure is, of course, open to argument. Every surgeon must follow his own predilections founded upon individual experience. I have always been afraid that, if I relied too much on what the radiologist could accomplish before operation, I might be tempted to do a less radical removal of the cancer and its surrounding areas. At any

rate, although for chosen patients I use radiation beforehand, in some cases I have felt disappointed in the results and in others I have failed to see the necessity for its use; and still I have looked upon proper postoperative radiation as a ready resource whenever a complete operation may have failed. The use of pre-operative radiation might likewise be considered useful, but in a few of the cases that received prolonged treatment by X-ray the skin and deeper areas were profoundly indurated, offering difficulties at operation; one case exhibited severe and almost uncontrollable oozing. Be that as it may, my object in referring to these methods is to emphasize my belief that any mammary cancer in the curable stage should be totally extirpated by a surgical operation done in the most adequate and finished manner possible. Methods of palliation or those used to prolong life over a certain period form no part of this discourse.

I wish to mention briefly and without tedious tabulation that I have records of 58 personal cases of cancer of the breast among those operated on from 1911 to 1929, all of whom lived beyond 5 years and some of whom are now living and well after 20 years. I have eliminated all who died from any cause whatever within 5 years after the operation, although I know that some of these did not die of cancer. The total number of operations (196) is unimportant, as I take it we are concerned here with reporting all our cured cases irrespective of percentages. Many of the cases as far back as 30 years ago were really inoperable but their breasts were removed to obviate local recurrence or for cosmetic purposes. At that time patients did not come so early; neither did we have improved radiology to help us. In point of time the first case of the series dates back to 1911; the patient was then aged 67 and lived about 15 years. The oldest patient was 70 years of age operated upon in 1914 and died in 1934 of pneumonia with pleural effusion. The youngest patient, 25 years of age operated on in 1915, is still living and well. Forty of the patients were white and 18 colored. The last patient included in the report was operated on February 20, 1929, and is now without recurrence. Less than half of all the patients received no radiation treatment. For the past 10 years practically every one had postoperative X-ray therapy; a few were radiated pre-operatively as well. Of the 58 patients fol-

lowed up to date and here reported as 5 year cures, 6 are considered to have died of metastasis after 5 years and 3 died of what appeared to be some form of malignancy after 10 years.

The remainder, 49 in number are either alive without recurrence or died of some intercurrent disease not connected with their breast cancers long after the limit of cure.

I am aware that this report sets no notable example. I am aware also, that the survivors represent the most favorable types of breast malignancy, both from the clinical aspects and from what we would now regard as pathological

grading. But I am equally conscious that here are all but a half hundred women who have lived out their expectancy as a result of the surgical removal of an organ affected with cancer from which they would eventually have died, if this dread disease had not been recognized in time. Failures there were many failures, not only in cases seen too late, but also possibly from imperfect judgment and technique. Yet here are the successful instances of which all of us have a goodly number. These are the cases to stress in our endeavor to prove that, taken in time, cancer is curable.

CANCER OF THE BREAST IS CURABLE¹

HUBERT A. ROYSTER, M.D. F.A.C.S. RALEIGH, NORTH CAROLINA

PRIMARY CANCER OF THE VULVA, VAGINA AND FEMALE URETHRA FIVE YEAR RESULTS¹

FREDERICK J. TAUSSIG M.D., F.A.C.S., St. Louis, Missouri

BEFORE proceeding to the body of this paper, may I continue briefly the 5 year statistics on cervical cancer reported at the Congress last year from the Barnard Free Skin and Cancer Hospital where Dr. Gellhorn and I have worked in alternate services for the past 28 years. To the 64 cures out of 566 cases (a percentage of 11.3) can be added 52 cases from the year 1928-29, with 12 cures. This makes a total of 615 cases with 75 cures, thus increasing the total percentage of cures to 12.3. Our operative results have been so much better than our radium results on early cases that I wish to endorse Dr. Gellhorn's statement of last year urging the retention of surgery in our armamentarium for the treatment of cervical cancer.

Primary cancer of the vagina is very rare and almost universally fatal. Out of a total of 27 cases which were observed previous to October 1929, at the Barnard Free Skin and Cancer Hospital, only 2 survived for more than 5 years, both were early cases treated with radium. This makes the percentage of cures only 7.5. Many were too far advanced for treatment or refused treatment, so that radiation was used in only 18 cases. We acknowledge our total inability to do anything effective for primary cancer of the vagina. Radical operation was done in one recent case with prompt recurrence.

Cancer of the female urethra is somewhat more encouraging. Taking only the 5 year cases at the Barnard Hospital and including 3 of my private cases I can report 14 patients with urethral carcinomata, of whom 4 survived the 5 year period of observation. Of these 4 cured cases, 1 is living and well now for 11 years, 1 died of heart disease at the age of 84, 11 years after treatment, 1 died of breast cancer 8 years later without local

recurrence, and 1 is living and well 5 years after operation. From Table I it will be noted that the best results were obtained by local excision or radiation combined with the double-Basset operation for removal of the tributary lymph glands.

At present I prefer to treat the urethra with radium or radon seeds, rather than attempt radical excision which is so often followed by recurrence of urine. In all favorable cases, radiation is combined with the Basset operation for removal of tributary inguinal and femoral lymph glands. Of 5 cases thus far operated on by this method there has been no fatality and only 1 recurrence.

This method of radical lymph gland removal is of even greater value in the treatment of carcinoma of the vulva. From 1906 to 1929, a time I have seen 101 cases of vulvar carcinoma. Of this number 77 were seen previous to 1929. Out of these 77 cases 10 were less advanced than those that were treated with radiation. Of the remaining 67 cases, 20 were five year cures and 47 were not, representing a percentage of 26 per cent. Most interesting of the results of various methods of treatment is shown in Table II.

In spite of the fact that 41 patients with cancer of the vulva were seen between 60 and 70 years of age, the incidence of the past 15 years is a radical lymph gland resection of the vulva and urethra. Out of 20

ling bladder been introduced of therapy dividing the the bladder reted as epithelial this report I representing In these 50 results with have been cured. However, the omata with r wall, and ing nodular by various this sym il epithelial nt one of the

including vulvectomy, there were only 2 post operative deaths (5.2 per cent), 1 death on the eighth day from heart failure and 1 on the twelfth day from cerebral embolism (Table III). In spite of many cases of infected wounds there were no deaths from sepsis. No fatalities from hemorrhage or operative shock were noted in this series, in spite of the long operations and proximity to the large vessels of the groin. I consider the Basset lymph gland resection a safe operation provided the surgeon has had a little training for it. My modification of Basset's original technique has been fully described in Curtis *Obstetrics and Gynecology* (Vol. 2). The essential features of this operation consist of laying open the entire inguinal canal, ligating the deep epigastric vessels and removing the deep glands situated to either side of the external iliac vessels. Then the superficial inguinal and femoral glands are freed *en masse* including all tissue and glands in Scarpa's triangle up to the femoral ring. By cutting Poupart's ligament better access is often obtained for the removal of the gland of Cloquet which is situated deeply beside the femoral vessels.

This operation is by no means limited to early cancers of the vulva. The contra indications are only (1) extension to the vagina (2) large lymph glands adherent to the femoral vessels (3) extreme old age or debility. In the last named group a simple vulvectomy must suffice. Counting only the cases on my own service seen in the past 10 years, I have done a complete Basset and vulvectomy on 24 out of 34 cases, an operability of over 70 per cent. In 2 additional cases a Basset was begun but could not be completed because of densely adherent lymph glands. It is evident therefore that I have not been selecting early cases. Assuredly it is encouraging if with an

TABLE III—BASSET OPERATION

	Total cases (1906-1931)			5 year cases (1906-1929 Oct.)		
	Num- ber	Oper- ative deaths	Cancer in glands	Num- ber	Cancer in lymph glands	% of over 5 years

Carcinoma of vulva	33		1	9	1	
Total	36	(1.7%)	13	12	2	1

operability of 70 per cent I have succeeded in obtaining 5 year cures in over 63 per cent.

The rationale of this method of treating cancer of the vulva is further supported by the microscopic examination of the removed lymph glands. Out of the 19 Basset operations done over 5 years ago cancer was found present in the lymph glands 13 times and yet in 6 of these there was no recurrence during the 5 year period. All of the 6 earlier cases without detectable gland involvement remained free of recurrence. Including the 14 cases of Basset operation done since 1929 we have a total of 33 with cancer present in the tributary lymph glands 22 times, or exactly two-thirds of the cases. The failure of X ray or radium to produce more than temporary regressions in such cancerous glands has been amply demonstrated by past experiences. Radical surgical gland removal, therefore, would seem to be positively indicated except in the presence of definite operative contra indications. Finally I should like to stress that absence of palpable glands does not mean absence of cancer any more than the presence of numerous large hard lymph nodes necessarily signifies that these contain cancer metastases.

SOME REMARKS ON FIVE YEAR CURES IN MALIGNANT TUMORS¹

EDWIN BEER, M.D., F.A.C.S. New York, New York

ALTHOUGH there is no doubt that various types of malignant tumors can be surgically removed and the host survive without any evidence of local or distant recurrence, it is impossible to be sure that the patient is not harboring an unrecognizable deposit. The peculiarities in the biology of malignant cells—whether they arise from normal cells by a process of localized natural selection or by mutation—are not sufficiently well understood to help us in determining when a patient is really cured. No test for the presence of residual growths is known, except possibly the prolan determination in testicular neoplasms and chorio-epithelioma. There is no doubt that secondary and even local deposits of cancer cells remain dormant for years, only to spring suddenly into active growth and lead to a fatal outcome. Years ago S. Olbert² reported such a striking dormancy in a melanosisarcoma of the choroid, which was treated by enucleation. Twenty four years later the patient developed signs of myelitis and at autopsy showed melanosisarcoma of lungs, heart, liver and first dorsal vertebra. All of us have seen analogous cases even though the period of dormancy may not have been so long.

As yet we do not know whether this peculiar behavior is intrinsic in the cancer cells or whether it is due to some inhibitive influence exerted by the host. Moreover in these unusual cases, we do not know what the life history would have been if the original growth had not been removed, though clinical experience suggests that as a practical proposition excision of the primary deposit should be axiomatic.

Having acted on this axiom many years ago, during recent months I have seen or heard from a number of patients that are well after radical operations for a variety of malignant conditions e.g.

1 A Wilms tumor of the kidney in an adult, 19 years after operation

2 A colloid carcinoma of the stomach, 15 years after operation

3 A carcinoma of the rectum 12 years after operation,

4 A carcinoma of the testis 17 years after operation

5 A carcinoma of the breast, 14 years after operation,

6 A number of cases of infiltrating carcinoma of the bladder, 11 to 13 years after operation

7 A carcinoma of the tongue, 15 years after the first operation.

I have been asked to furnish this symposium with my results especially in bladder and kidney neoplasms and have recently reviewed the 5 year cures for this occasion. What the exact value of a review and enumeration of disconnected cases is, I cannot quite grasp. We know that we can cure a certain number of carcinoma cases. The patient however, wishes to know what his chance of a 5 year cure is, and there we are likely to stumble. In the individual case, despite studies in microscopical grading and microscopical determination of radio sensitivity it is practically impossible to tell the individual patient what his chances are, even if we are lucky enough to get the case early. In general we can say that the earlier we get the cases, the better the outlook, and therefore the profession should aim at early diagnosis. Even advanced cases however, may be cured, and should be given the chance. A valuable contribution would be the determination of the percentage of cases in certain groups as they come to operation, that are cured for 5 years or more, rather than an enumeration of so many individual cases of a type of malignancy cured for 5 years or more by one or more surgeons. In my subsequent analysis, I have attempted this.

As a result of attempts at grading bladder tumors, considerable confusion has been introduced into the study of end results of therapy. I can see no adequate excuse for so dividing the epithelial growths developing in the bladder that benign papillomata are interpreted as epithelial carcinomata Grade I, and in this report I have excluded all such papillomata, representing some 248 cases from my discussion. In these so called Grade I carcinomata, my results with transurethral electrocoagulation have been curative in the great majority of cases. However, the results obtained in papillary carcinomata, with and without infiltration of the bladder wall, and solid carcinomata, infiltrating ulcerating nodular and more or less papillary, treated by various forms of therapy, fit properly into this symposium. These cases represent the real epithelial malignancies of the bladder, and present one of the major urological problems of the day. A variety of therapeutical efforts has been applied to these

¹Zentralbl. f. Chir., 1906, p. 509

²Presented in the symposium, Cancer I. Carable before the Clinical Congress of the American College of Surgeons, Boston, October 17, 1914.

cases, and limiting myself to cases treated or operated upon prior to 1930 I find that we have the following results:

1. Non-infiltrating carcinomata, 11 cases cured by transurethral fulguration or electrocoagulation with high frequency current, representing 55 per cent of total so treated and not lost to follow-up.

2. Non-infiltrating or moderately infiltrating, papillary carcinomata, 4 cases cured by transurethral radium, usually with electrocoagulation, representing 11 per cent of the total so treated and not lost to follow up.

3. Infiltrating papillary carcinomata involving the bladder wall more or less diffusely 10 cases cured by operative excision according to the technique described by me in 1917^{1,2,3} representing 55.5 per cent of the total so treated and surviving the operation and not lost to follow-up.

4. Infiltrating, solid, ulcerating, more or less papillary carcinomata, diffusely involving the bladder wall, 14 cases cured by extensive resections, frequently with re-implantation of the ureter according to the above mentioned technique, representing 40 per cent of the total so treated and surviving the operation and not lost to follow-up.

5. Infiltrating solid, ulcerating more or less papillary carcinomata diffusely involving the bladder wall, 2 cases cured by suprapubic cystostomy and implantation of radium emanation seeds, representing 10 per cent of the total so treated and surviving the operation and not lost to follow-up.

6. Very extensive, solid, ulcerating more or less papillary carcinomata, diffusely involving the bladder wall, 4 cases cured by total cystectomy representing 57 per cent of the total so treated and surviving the operation.

With cauterization, diathermy or electric cautery or Paquelin cautery and deep X ray there have been no 5 year cures in carcinomata infiltrating more or less diffusely the bladder wall.

In summary therefore, in these 6 groups of definite carcinomata, I can report 45 cures in

cases treated prior to 1930. It must be borne in mind that owing to the advanced age of many of these patients when they present themselves for treatment, their life expectancy scarcely warrants a 5 year survival, and many more cases were apparently cured in each category for periods of less than 5 years, but sufficiently long to consider cured.

The results in kidney malignancies must be divided into two categories, (1) the hypernephromata or clear cell carcinomata, the adenocarcinomata, the papillary and squamous cell carcinomata in adults, and (2) the embryomata, Wilms tumors and sarcomata usually seen in childhood.

In children prior to 1930 in Wilms tumors or embryomata we have no 5 year cures. It is hoped that pre-operative radiation followed by nephrectomy may improve our results. One case of hypernephroma in a child, however, was cured for over 5 years, giving in this group of 7 nephrectomies only 14.66 per cent cures. In view of the fact that all kidney tumors in children are not necessarily embryomata and in view of the fact that embryomata may vary in their malignancy the operative removal of such tumors should be regularly carried out.

In adults prior to 1930, we have 7 five year cures in kidney tumors of the hypernephroma and adenocarcinoma and papillary carcinoma type, 1 five year cure in a large embryoma or Wilms tumor and 1 five year cure in a carcinoma of the ureter or 9 cases in all out of 34 surviving the operation and followed, making 26 per cent plus.

In concluding it must be emphasized that in view of the fact that the postoperative follow-up of the whole series of kidney tumors has been incomplete, the percentage of 5 year cures based on survival after operation and 5 year follow-up may represent a maximum percentage of cures whereas in bladder tumors, when repeated cystoscopic check up (usually disagreeable to the patient) is possible, it probably represents a minimum percentage of cures. These patients after several negative cystoscopies tend to be chary and refuse check up (and this applies to doctors as well as other patients) in this way diminishing the number of 5 year cures.

FIVE YEAR CURES OF CANCER OF THE RECTUM BY THE RADICAL ABDOMINOPERINEAL EXCISION¹

A. LAWRENCE ABEL, M.S. (LOND.), F.R.C.S. (ENG.) LONDON ENGLAND

Late Huxterus Professor Royal College of Surgeons of England; Surgeon attached to the Staff of the Cancer Hospital, the Gordon Hospital for Rectal Diseases, the Princess Beatrice Hospital, the Woolwich Memorial Hospital

THE cure of cancer of the rectum depends upon three main factors (1) the knowledge of the pathological paths along which the growth spreads, (2) the planning of an operation to include as much as possible of the fields of spread, (3) careful pre-operative, operative, and postoperative treatment.

1 The way in which cancer of the rectum spreads is too well known to need repetition here, except to remind ourselves that it occurs (a) in a downward direction to the ischio-rectal fossa, (b) in a lateral direction on the levatores ani muscles, and (c) most important of all, in an upward direction along the course of the inferior mesenteric artery, and thence laterally toward the wall of the pelvic colon.

2 Three main principles of surgery are involved in operating upon cancer of the rectum (1) Not only the growth but also all removable fields of lymphatic spread must be extirpated as widely as possible. In this instance the upward spread demands the most careful attention, and should be removed just up to the point where the left colic artery arises from the inferior mesenteric artery (2) Where an operation involves two different fields of maneuvers of which one is sterile and the other relatively infected, the aseptic field should first be dealt with and closed off, and the infected area should be dealt with last, in order that the former may not be infected from it. (3) Before a primary growth is tampered with or manipulated in any way the blood and lymph vessels, which are liable to transmit metastatic cells into the venous and lymphatic circulations, should be ligated. Primary dissection should be carried out as far as possible from the original growth.

The only operation which fulfils these fundamental principles is the radical abdominoperineal excision introduced in 1907 by my friend and senior colleague, Mr W. Ernest Miles.

3 *Pre-operative, operative and postoperative treatment* In the pre-operative treatment, the following measures are followed (1) Care is taken to ensure that the patient's general health, blood pressure, pulse pressure and cardiac index, together with renal and other vital functions, are satisfactory (2) Dehydration is combated and

no purgation is allowed for 48 hours before operation. (3) Careful attention is paid to the state of the patient's bowels and any suspicion of obstruction is treated by performing a cæcostomy or colostomy some days before the radical operation. In other cases a 5 to 7 day course of careful colon wash-outs is carried out. (4) Any lack of hæmoglobin or erythrocytes is combated by a preliminary blood transfusion (5) Careful premedication is used—my routine is two-thirds grain pentopon and 1/510 grain scopolamine one hour beforehand.

In the operative treatment during operation we find that the use of a spinal injection of 1-1500 percaïne markedly diminishes shock. Ether and chloroform are rigorously excluded, and nitrous oxide oxygen is employed as the general anæsthetic.

About 10 years ago I introduced a blood transfusion as a regular routine postoperative practice for all cases, and for the last 2 years have, in addition, been giving continuous intravenous infusion with glucose-saline for the first 24 hours, and sometimes longer, after the operation and meanwhile all fluids by mouth are withheld.

In my opinion the most important new lines in technique have been (1) the routine use of spinal anæsthesia, (2) the employment of nitrous oxide oxygen (3) careful pre-operative care of the intestine, (4) pre-operative building up of natural reserves, (5) absolute aseptic intestinal division, (6) presacral neurectomy, and the avoidance of urinary infection, (7) immediate routine post-operative blood transfusion, (8) continuous intravenous glucose saline infusion. These measures have had a definite influence upon the mortality of the operation, which is steadily improving.

Five year cures I have the honor to report on 164 survivals after this operation, operated on by the staff of the Cancer Hospital, London, during the 10 year period 1920 to 1929 inclusive.

You have asked me to analyze my cases on a pathological basis and under the following headings (1) incipient, cancer (localized) without gland involvement, (2) cancer that has extended to the lymph nodes (3) extensive local invasion with metastases (4) recurrent cancer

As this type of growth in Group 4 is not suitable

for the operation it has perforce to be omitted. In 70 of the total series the exact pathological condition is known. These are analyzed in Table I.

TABLE I

	Group	No.	Died in less than 5 years	Alive and well after 5 years	Untraced	Percent age of 5 year cures
Rectovesical	I	6		5		83
	II	5				20
	III	8	7			14
Vaginal	I			16		7
	II	9		5		70
Anal canal	I					0
	II					
Totals, here pathological condition is known		70		5	5	57.5

From this the following facts emerge. Early cases without glandular involvement have on the whole a higher 5 year cure rate than the more extensive ones. In the central portion of the

rectum this radical operation is as efficacious in effecting a 5 year cure in those with lymph nodes involved as in those in which lymphatic invasion cannot be demonstrated pathologically.

Of the total series of 164 survivals, 47 cases died within 5 years of the operation, 104 were alive and well 5 years and more after and 14 are untraced.

TABLE II—COMPLETE SERIES

Survivals	164
Died in less than 5 years	47
Alive and well after 5 years	104
Untraced	14
Percentage of 5 year cures	63.4

Out of all survivals 63.4 per cent were known to be alive and free from signs of the disease 5 years after the operation. If the untraced cases are ignored 104 out of 150 cases traced represent a 5 year cure rate of 69.3 per cent.

I have to express my thanks to my colleagues the Staff of the Cancer Hospital, for their kindness in placing their material at my disposal. I also wish to convey to you and the Board of Regents of this illustrious College my heartiest and humblest thanks for the great honor you have done me in asking me to present the results of our work to you today.

MALIGNANT DISEASES OF THE MOUTH, PHARYNX AND LARYNX
FIVE YEAR CURES¹GORDON B NEW M.D. F.A.C.S., AND FREDERICK A. FIGI, M.D., F.A.C.S. ROCHESTER, MINNESOTA
Section on Laryngology Oral and Plastic Surgery The Mayo Clinic

WE are reporting 745 cases of malignant disease of the mouth, pharynx and larynx, in which patients have survived 5 or more years without recurrence. Treatment in these cases has been by surgical operation surgical diathermy and radiation, depending on previous treatment, situation of the lesion, type of growth presence or absence of involvement of lymph nodes, and the patient's age and general condition.

Patients surviving 5 years or more after treatment of a malignant growth of the upper jaw and antrum numbered 127 (2). The primary tumors of the antrum are those that apparently originate in the antrum itself the secondary tumors of the antrum are those that originate apparently in the upper jaw and extend into the antrum. The tumors of the upper jaw and palate are those which are situated in the regions named without involving the antrum. Growths were destroyed by surgical diathermy and irradiation applied either through the mouth or after lateral rhinotomy. The end results in this group of cases are shown in Table I.

Patients surviving 5 or more years after operation for carcinoma of the lower jaw numbered 90. In these cases the growth was destroyed by surgical diathermy and the submental and submaxillary lymph nodes were removed, if the mucous membrane of the cheek or floor of the mouth was involved. In addition to this, radiation was used both locally and externally over the lymph nodes of the neck in the indicated cases. The end-results in these cases are given in Table II.

TABLE I—MALIGNANT GROWTHS OF UPPER JAW AND ANTRUM 127 PATIENTS SURVIVING 5 OR MORE YEARS AFTER TREATMENT

Situation of growth	Patients treated	Patients traced	Lived 5 or more years after treatment	
			Number	Per cent of traced patients
Antrum, primary	91	78	30	40
Antrum, secondary	30	43	23	53.4
Upper jaw and palate	154	118	74	62.7
Total	295	239	127	53.2

Five or more years after treatment for carcinoma of the lip 357 patients operated on between 1919 and 1927 were surviving (1). In general the primary lesions are widely excised and the bilateral submental and submaxillary lymph nodes are removed. In many cases in which the primary lesions have received previous treatment it is necessary to remove the lesion by means of surgical diathermy or the cutting cautery and to delay plastic closure or reconstructive operation until there is a reasonable chance of the lesion not recurring. If a submental or submaxillary node is involved an upper deep cervical dissection is done on the involved side. Radiation is used in addition, particularly in cases in which lymph nodes are involved. The end results in this group of cases are recorded in Table III.

Patients surviving 5 or more years following treatment for carcinoma of the tongue numbered 58. The local lesion in cases of this sort is treated by means of surgical diathermy, complete removal of the lesion by cautery, insertion of radium or a combination of these, depending on the situation, extent, and type of growth. Radiation is administered by means of radium emanation seeds or radium element points introduced into the primary lesion. The lymph nodes of the neck are removed except in epitheliomata of malignancy graded IV, followed by irradiation. In Table IV are given the end results in this group of cases.

There were 44 patients surviving 5 or more years after treatment of malignant tumors of the pharynx and tonsil (3). This group does not include the nasopharyngeal tumors. Primary lesions of low grade of malignancy are removed

TABLE II—MALIGNANT GROWTHS OF LOWER JAW 90 PATIENTS SURVIVING 5 OR MORE YEARS AFTER TREATMENT

Lymphatic involvement, cases	Patients operated on	Patients traced	Lived 5 or more years after operation	
			Number	Per cent of traced patients
Nodes involved	45	33	1	3.0
Nodes not involved	145	113	79	69.9

Total	75	116	56	48

*Cases in which there was extension to the floor of the mouth not included.

†Nodes not dissected because of type of growth, age of patient, and so forth.

with the cutting cautery or by diathermy and this is followed by removal of nodes of the neck. For lesions of a high grade of malignancy and for lymphosarcomata, radiation is applied by introducing the agent directly into the primary lesion and placing it externally on the neck. For adenocarcinomata of mixed tumor type, the tumor is removed through the pharynx or the side of the neck, depending on where the largest portion presents. In Table V are shown the end-results in this group of cases.

Five or more years after operation, 69 patients who had carcinoma of the larynx were surviving (4). For tumors of low grades of malignancy and in early cases, we perform thyrotomy and remove the growth, destroying the base of it by surgical diathermy. In more advanced cases, the cartilage is removed along with the growth. In a small

TABLE V.—MALIGNANT GROWTHS OF THE PHARYNX AND TONSIL 44 PATIENTS SURVIVING 5 OR MORE YEARS AFTER TREATMENT

Total	69	9	13

group of cases in which the anterior commissure is involved, this is removed in one piece, after division of the hyoid bone and examination is made through the thyrohyoid membrane. For growths of the epiglottis preliminary tracheotomy is performed, and the primary lesion is removed by surgical diathermy under suspension. In more advanced cases of tumor of the epiglottis, aryepiglottic fold, and base of the tongue, pharyngotomy is used. In cases in which there is fixation of one side of the larynx, with involvement of the anterior commissure, and the lesion is of a high grade of malignancy laryngectomy is performed. Radiation is used before and after treatment of the more malignant lesions. The end-results in these cases are shown in Table VI.

FIVE YEAR SURVIVALS IN LYMPHATIC TUMORS¹

LLOYD F CRAVER, M.D. NEW YORK, NEW YORK

FIVE year survivals following treatment of Hodgkin's disease, lymphosarcoma, and leucemia by irradiation are few. Some writers doubt that the average duration of life following onset of these diseases can be increased by the use of X rays or radium. This question cannot readily be answered by statistics, largely because the great variations in duration of the natural course impair the value of averages.

However, the dramatic primary regressions, and the lessening or disappearance of symptoms that are brought about by irradiation in numerous individual cases, suggest that life has been prolonged in these instances, at least, and fully justify the continued use of X rays and radium in these fields.

The following four tables show the 5 year survivals in cases of Hodgkin's disease, lympho-

sarcoma, myeloid leucemia and lymphatic leucemia admitted to Memorial Hospital between 1917 and July 1 1929.

What can be done to improve these figures? In this entire group betterment of the patients' living conditions approaching a general régime as for tuberculosis will help to prolong survival. The various adjuvants, such as heliotherapy, arsenic, iron, liver, transfusions, and surgical removal of localized processes, cannot be discussed here.

As for the results by irradiation alone early diagnosis, except in the naturally acute forms of the diseases, with early judicious treatment, not necessarily heavy irradiation, will improve our figures.

TABLE I—HODGKIN'S DISEASE—FIVE YEAR SURVIVALS

	Number	Per cent	Average survival since admission—years
All cases	115	100	1.9 (excluding 4 cases followed less than 6 months)
Total 5 year survivals	15	13	7.5
Alive 5 years on 7-1-34	6	4.8	6.9
Alive 5 years and N.E.D. on 7-1-34	4	3.5	10.5

4 survived over 7 years.
Longest survival, 13 1/2 years, now N.E.D. Rooper lymphogranuloma malignum with much fibrosis.
No evidence of disease.

TABLE II—LYMPHOSARCOMA—FIVE YEAR SURVIVALS

Longest cases 5 1/2, 8 1/2, and 7 7/8 years.

THE SURGICAL TREATMENT OF CANCER OF THE STOMACH¹

J. SHELTON HORSLEY, M.D., F.A.C.S., RICHMOND, VIRGINIA

From the Surgical Department of St. Elizabeth's Hospital

ABOUT one-fourth or one third of the 120,000 deaths from cancer every year in the United States is from cancer of the stomach.

There is no real problem as to what the treatment of gastric cancer should be. Practically all malignant tumors of the stomach, except the rare lymphosarcoma and the unusual small round cell carcinoma from the deeper layers of the mucosa, are radioresistant. With improvement in the technique of radiation doubtless some further beneficial effect can be derived from this source but with the liver overlying the stomach and the pancreas behind it, an amount of radiation that would materially affect a gastric cancer that is even mildly radioresistant would doubtless play havoc with these two vital organs. We may say then that while in some instances radiation is an adjuvant, in the vast majority of cases of cancer of the stomach there is only one remedy: surgical excision, which is remarkably efficient if applied early. Thus Balfour reports that in his records about 50 per cent of the patients in whom gastric carcinoma confined solely to the walls of the stomach has been widely removed are alive and without recurrence 5 years after operation.

CLASSIFICATION OF OPERATIONS FOR GASTRIC CANCER

The surgical therapeutics for cancer of the stomach may be divided into 6 different classes, 3 of them with a view to cure, and 3 solely for palliation. The Billroth I operation, the Billroth II operation and total gastrectomy may be listed as curative operations while gastro-enterostomy, the Devine operation, and gastrostomy are only palliative.

In the first division is cancer of the pyloric end of the stomach in which it is possible to do a reasonably wide resection and then unite the stump of the stomach to the duodenum. Operations which proceed along this line are classified under the title of the Billroth I method, and the various techniques such as the Finney-Häberer and others that accomplish this are termed modifications of the Billroth I.

In the second division are the more extensive cancers of the pyloric portion or of the middle body of the stomach in which it is not possible to bring the stump of the stomach to the duodenum so the duodenum must be closed and an anasto-

mosis made to some portion of the jejunum. This is known as the Billroth II method of operation and the various types of it as the Polya, Hofmeister and Balfour techniques, are called modifications of the Billroth II principle.

In the third division, the stomach is extensively involved without surrounding metastases, or the cardiac portion is affected, and here a total gastrectomy may be indicated. This operation of course, is applicable to only a comparatively small number of cases.

In certain non-resectable cases of gastric cancer often some palliative operation is indicated. It is doubtful if gastro-enterostomy has any place in the treatment of cancer of the stomach. It certainly has a very limited field, which is apparently vanishing. If the patient has a large mass in the pyloric end of the stomach and there are a few metastases outside of the stomach or a small metastasis in the liver doubtless a partial gastrectomy removing the slooing septic mass, will make the patient more comfortable and probably give a longer life than a gastro-enterostomy would.

PREPARATION, ANESTHESIA AND AFTER TREATMENT

The pre-operative and postoperative treatment in all cases of cancer of the stomach is extremely important. Several times a day the patient should have a gastric lavage under low pressure. Dehydration is corrected largely by proctoclysis, hypodermoclysis or the intravenous administration of dextrose in Ringer's solution which latter procedure we have found particularly satisfactory. Transfusion of blood is often indicated.

Following the suggestion of W. H. Higgins, of the staff of St. Elizabeth's Hospital we began about 10 years ago giving patients who were to be operated upon for gastric cancer large quantities of dilute hydrochloric acid for several days before the operation. This has a marked antiseptic effect and lessens the danger of peritonitis. Some intraperitoneal vaccine such as that of Steinberg may also be helpful in preventing infection.

The anesthetic should be carefully chosen. In many cases operations for gastric cancer can be done under local anesthesia, supplemented if necessary by ethylene or by nitrous oxide and

¹Presented at the 27th session, on the Treatment of Cancer, before the Clinical Congress of the American College of Surgeons, Boston, October 17, 1934.

oxygen, and frequently if morphine and scopolamine are given it can be completed under a local anæsthetic, infiltrating just beneath the peritoneum after the method of Finsterer

MODIFICATION OF BILLROTH I OPERATION

I shall not attempt to describe all of the different operations for cancer of the stomach, but shall only give those that appear to me to be the most satisfactory. Some modification of the Billroth I technique can be applied more frequently than it is used, but metastases of gastric cancer are prone to extend along the lesser curvature of the stomach, and an attempt to make a satisfactory approximation of the stomach to the duodenum should not prevent a sufficiently wide excision. The point of resection should be at least 4 centimeters beyond the apparent margin of the cancer. If more of the stomach than this can be removed without impairing the conditions for the operation, it should be done. The first procedure after opening the peritoneal cavity, is inspection of the abdominal contents, feeling in the pelvis for metastases in the cul-de-sac, and examining the liver and the lymph nodes under the diaphragm. If there is no contra indication for a radical operation and a Billroth I type of operation is applicable, the gastrohepatic omentum is opened. If the operation is done under local anæsthesia, the tissue just beneath the posterior peritoneum above the pancreas and up toward the diaphragm on both sides of the spinal column are thoroughly infiltrated with 0.5 per cent novocain solution to which has been added about 2 drops of 1:1000 adrenalin solution to the ounce. If the needle is inserted just under the peritoneum no damage to the deeper structures will occur and the solution will infiltrate freely and block off all of the nerves in the region.

The vessels along the lesser curvature of the stomach at the proposed point of resection are doubly clamped and divided preferably with the electric cautery. The gastrohepatic omentum, which is usually quite thin, is doubly clamped and divided about its center and the vessels to the pyloric end of the stomach are similarly treated being divided with the electric cautery. The stomach is lifted up, making all movements as gentle as possible, not only to prevent shock but to avoid transplanting cancer cells. Gauze moistened with salt solution is placed in the lesser peritoneal cavity. The stomach is lifted up with the hand, and with the fingers the gastrosplenic omentum is pushed up. The proper point of division along the lower border of the stomach is selected, the gastrosplenic omentum is incised, and

the vessels are doubly clamped and divided at the greater curvature. Then the gastrosplenic omentum is doubly clamped and divided in sections toward the pyloric end of the stomach, keeping close to the colon. When the pyloric end of the stomach is reached special care is taken to avoid injury of the mesenteric vessels of the transverse colon. By lifting the stomach well up in this region and by separating any adhesions and pushing down the transverse mesocolon injury to its vessels can usually be avoided, but it is highly important to remove as much tissue as possible from around the pyloric end of the stomach.

The blood vessels are controlled by transfixing and tying each clamped segment with plain catgut. The ends of some of these ligatures are left long. Two ligatures are placed on the stump of the vessels along the lesser curvature, and the one nearest the point of division is left long. This is to avoid the possibility of the ligature in this region slipping. The portion of the stomach to be resected is thus isolated entirely, except for its continuity with the rest of the stomach and with the duodenum. Two stout Payr clamps are placed on the body of the stomach as close together as possible. Two clamps preferably pedicle clamps such as the Ochsner or Kelly forceps, are placed on the duodenum just beyond the pylorus. The duodenum is divided between the clamps with the electric cautery, and then the stomach is incised between the two Payr clamps with the electric cautery, taking care to canterize the stump of the stomach thoroughly so that the Payr clamp is heated sufficiently to char the tissues within its grasp. This not only kills any cancer cells that may be in the grasp of the clamp and so adds somewhat to the chances of cure, but also tends to control bleeding. The stump of the stomach is brought over to the stump of the duodenum. If there is not sufficient undersurface of the duodenum exposed the pancreas is dissected back, preferably with a few light strokes of the electric cautery.

In many instances when the stump of the stomach apparently cannot be brought over to the duodenum, the stomach may be mobilized by slipping the hand under the cardiac end, stretching or dividing any adherent bands, and dividing the gastric artery if necessary. Often these manipulations will be so effective that even a small remnant of stomach which at first it seems impossible to bring over can be mobilized and sutured to the duodenum without tension.

Beginning at the upper border, a series of interrupted mattress sutures of 00 tanned or chromic

catgut is placed uniting the posterior surface of the stump of the duodenum to the upper portion of the posterior surface of the stump of the stomach. All of these sutures are placed before any one is tied (Fig. 1). When they are tied the ends of the upper and of the lower sutures are left long as tractor sutures. The clamp is removed from the stump of the duodenum and any regurgitant duodenal content is removed with a suction apparatus. Bleeding vessels are clamped with small hemostats. The Payr clamp on the stump of the stomach is removed, bleeding points are clamped and the gastric contents are withdrawn with a suction apparatus. The stomach of course, should have been washed out a short while before the operation. Occasionally in marked pyloric obstruction gastric lavage will not remove all of the contents of the stomach in some cases I have found food, such as corn or beans, that was eaten several days before. If it is suspected that this may occur there is placed among the instruments a small soup ladle, with which the contents of the stomach can be ladled out, after which the stomach is cleaned with salt solution. If the surrounding tissues are well protected with moist gauze, and care is used in the ladding, but little soiling occurs, and if abundant hydrochloric acid has been given for several days before the operation this material should not be very septic.

No effort is made to trim away the margins of the crushed tissue. A study of the sutured intestine and stomach shows that the margin of the wound always degenerates and tissue that is held by sutures firmly enough to produce complete hemostasis will slough off so that trimming away the margins of crushed or charred tissue is of no advantage so far as eventual healing is concerned, causes an additional loss of blood, and unnecessarily exposes fresh surfaces to the contents of the stomach and duodenum.

A suture of No. 1 tanned or chromic catgut is begun, going from the mucous membrane on the upper border of the stump of the stomach outward, returning through the upper border of the stump of the duodenum from without inward. This knot is tied several times, and the short end is clamped. If the stump of the stomach is large its lower portion is clamped with a pedicle forceps. This suture is continued downward as a lock stitch, snugly uniting the posterior margin of the stump of the stomach to the posterior margin of the stump of the duodenum (Fig. 2). When the lower border of the duodenum is reached, its anterior wall is incised for $1\frac{1}{4}$ to $1\frac{3}{4}$ inches (3 to 4 cm.) This incision should be just below the center of the anterior surface of the duodenum,

and its location is accurately ascertained by putting the finger into the duodenum. This incision flares open the duodenum and permits about two more stitches of the continuous lock stitch, uniting the stomach to the duodenum. Then the suture is continued over the redundant lower portion of the gastric stump and tied at the greater curvature (Fig. 3). Occasionally by flaring open the duodenum thus, if the stomach is not large, an end-to-end union can be made but usually there is a redundancy of the stump.

A second suture is begun as the first suture, passing from within outward at the lesser curvature of the stomach and from without inward at the upper border of the duodenum. After tying this suture, its short end is tied several times to the short end of the preceding suture. This makes for additional security. This suture is carried anteriorly as a continuous stitch. Where there are bleeding vessels, an additional loop of the stitch is taken to secure hemostasis. The suture is placed as far as possible from within, being tightened only on the left side as it emerges from the stump of the duodenum while pressure is made just behind it, as shown in the illustration. In this way not only is hemostasis secured, which cannot be satisfactorily done by the continuous mattress suture, but the raw margins are inverted almost as though the suture were applied entirely from within (Fig. 4). When the lower border of the duodenum is reached this suture, too, is continued onto the redundant stump of the stomach and terminates at its lower border. A suture of No. 00 tanned or chromic catgut is begun as a purse-string suture at the lower border of the stomach, invaginating the redundant test (Fig. 5). It is then carried upward, as a continuous mattress or right angle suture with an occasional backstitch, and terminates at the upper border of the stomach. At this point the ligatures on the vessels at the upper border of the duodenum and on the vessels of the lesser curvature of the stomach are tied together and over them is inserted a purse-string or a mattress suture of No. 00 tanned or chromic catgut, still further invaginating the tissues. This region is particularly subject to peristalsis and traction, and additional suturing here is advisable. At the lower border where the redundant test of stomach was tucked in, a purse-string suture of No. 00 tanned or chromic catgut is placed, and after it is tied the ends are passed through adjacent peritoneal covered fat and are again tied. A few additional interrupted sutures of No. 00 tanned or chromic catgut may be placed anteriorly and if peritoneal covered fat is handy it is also caught in the suture.

Fig. 1 The segment of the stomach has been removed. The posterior margin of the stump of the stomach is sutured to the posterior margin of the stump of the duodenum with interrupted mattress sutures of fine tanned or chromic catgut. All of the sutures are placed before any one is tied.

Fig. 2 The internal row of sutures is being applied uniting the posterior margin of the stump of the stomach to the posterior margin of the stump of the duodenum. The dotted line shows where the incision will be made in the duodenum to flare it open.

This operation I have been doing with much satisfaction for the past 10 years in cancer of the stomach and in ulcers of the pyloric portion of the stomach. Its advantages are that the pathological lesion is excised and the physiological function of the stomach is restored as nearly as possible to normal. The physiologically active lesser curvature of the stomach is aligned with the upper border of the duodenum which is its normal relationship. The physiologically inactive greater curvature is easily folded in. The great objection to the original Billroth I operation, the so called "deadly triangle" which occurred when the stump of the duodenum was aligned to the greater curvature of the stomach, is avoided. By invaginating the gastric stump along the greater curvature where it is quite mobile and by bringing over peritoneal covered fat, this region is made secure. Flaring open the duodenum after it has been fixed by sutures does not displace its relationship to the upper border of the stomach and at the same time gives a wide opening which prevents contraction and will doubtless be a sufficient exit for

food even if recurrence of the cancer makes some obstruction in this region.

The field of operation is limited to the vicinity of the lesion and does not involve the possibilities of spreading bacterial infection or cancer cells to the other organs or to tissues below the transverse mesocolon, which might be possible in the types of Billroth II.

It is well known that in many cases of cancer of the stomach there is some free hydrochloric acid in the gastric juice. If there is no free hydrochloric acid at the time of operation and the patient is cured by removing the cancer it may be reasonably assumed that the secretion of hydrochloric acid will be resumed in at least some cases. Physiologists have shown that the sensitiveness of the intestinal mucosa to hydrochloric acid increases from the duodenum down, and that the duodenum normally has far more resistance to hydrochloric acid than any other portion of the intestinal tract. It is readily conceivable that what not infrequently happens in partial gas-

Fig 3 The duodenum has been cared open and the posterior row of sutures is about completed

treotomy for peptic ulcer in which the Billroth II type of operation is done—development of a jejunal ulcer—may occasionally occur in partial gastrectomy for cancer when the Billroth II type is done. Thus, Fordyce B St John has reported a case of death from jejunal ulcer which followed some time after a Polya type resection for cancer of the stomach.

The technique described most often be modified to suit the conditions. If for instance, there are adhesions along the head of the pancreas, it will be best to divide the stomach between the Payr clamps and dissect it toward the pyloric end preferably with the cautery and if necessary include a small portion of the pancreas in the dissection. If there seem to be adhesions and special involvement along the lesser curvature, the gastroduodenal omentum should be first opened and then the stomach can be divided between the Payr clamps, the duodenum between clamps, and finally the dissection made toward the lesser curvature.

In occasional cases the transverse colon is involved, so in order to maintain the principle of block dissection the gastrophrenic omentum is first divided in segments, the stomach doubly clamped and divided about its middle, and the duodenum also divided. The stomach is then lifted up, the mesocolon is divided in segments, and the regions for section of the transverse colon

are doubly clamped and divided with the cautery thoroughly charring the stumps. The stomach is then united to the duodenum, as has been described, and lastly, the stumps of the transverse colon are treated. The kind of treatment depends largely upon the condition of the patient. If the patient is quite fat, or if his condition is not good, it will doubtless be best to bring the stumps of the colon into the wound, leaving the clamps upon them, and to do a right colostomy through a muscle splitting incision bringing up the first portion of the ascending colon onto the abdominal wall placing a glass rod beneath it, and then opening the cecum. This procedure would probably be indicated even with a direct anastomosis of the colon, which may be advisable when the patient is thin with an empty bowel.

The type of operation described has, I think, a far larger field than has been generally credited to it. Undoubtedly however there are many cases in which the stump of the stomach cannot be satisfactorily united to the duodenum, and here some type of Billroth II operation should be done.

MODIFICATIONS OF BILLROTH II

The most popular type of Billroth II is the Polya operation, in which the jejunum is brought up through a rent in the mesocolon and sutured to the stump of the stomach as an end-to-side union. If it is possible to do so the anastomosis is drawn down through the rent in the mesocolon, so it lies below the mesocolon and resembles a posterior gastro-enterostomy.

In some instances, when this is difficult, the modification introduced by Balfour is excellent, bringing the jejunum over the colon and suturing it to the stump of the stomach. When this procedure is adopted a long loop of jejunum should be chosen because the oral end of the loop if too short swells and may cause obstruction. An entero-anastomosis should be made between the two limbs of jejunum, just below the transverse colon.

The Hofmeister modification of the Billroth II appears to me to be better than the usual Polya. In the Hofmeister operation, which is particularly applicable when the stump of the stomach is very large the upper portion of the stump is closed by sutures and the lower half or third is left open and anastomosed to the jejunum end-to-side (Fig 6). In such cases it will be less difficult to bring down the lower portion of the stump of the stomach for the anastomosis than to bring down all of it, as with the Polya operation. One objection to the Hofmeister operation is that if the incision of the

Fig. 4. The anterior row of sutures, which was begun as explained in the text, is continued downward in such a way as to invert the margins of the stomach and duodenum. The suture is drawn taut only as it emerges from the duodenal mucosa, while pressure with the thumb or finger is made on the wound behind the suture.

gastrectomy is made in such a manner as to leave a marked redundancy along the greater curvature, infolding of the upper portion of the stump may convert the lower portion into a kind of snout and produce occlusion. To avoid this, the incision in the stomach should be made with a distinct slant from the lesser curvature downward and to the left. Even then, if there appears to be too much redundancy, the lower portion of the stump should be cut away.

TOTAL GASTRECTOMY

While total gastrectomy has a limited field this field is definite and with improvement in technique, and in the pre-operative and postoperative care of the patient, this operation will be more often indicated.

In total gastrectomy infection is more likely to occur than in partial gastrectomy, and drainage should usually be provided. In this operation the

Fig. 5. A purse-string suture of fine tanned or chromic catgut is placed at the lower portion of the stump of the stomach, inverting the redundancy.

attachments to the stomach along the greater and lesser curvatures are severed as in a partial gastrectomy. A rubber catheter is inserted at some portion of the stomach where the wall seems to be normal and fastened with a purse-string suture of linen which also transfixes the catheter. Another purse string suture buries the catheter still further (Fig. 7A). The catheter is connected at intervals with a suction apparatus and so draws off gas and the fluid contents of the stomach. In this way regurgitation into the esophagus that might be caused by lifting up the stomach is avoided. Thus regurgitated fluid may flow back again into the abdomen when the esophagus is divided. The attachments to the spleen are delicate and must be carefully clamped and divided. Thorough hæmostasis is made. The clamped tissue is controlled by transfixing and tying it with plain catgut. The duodenum is doubly clamped with pedicle clamps and divided with the cautery. The stomach is lifted up using suction through the catheter at intervals. The stomach thus forms a kind of handle for the esophagus, a valuable suggestion of Moynihan.

The loop of jejunum for the anastomosis is chosen with special reference to having the oral part of the loop sufficiently long to reach the diaphragm not only without tension, but with a redundant portion of it hanging well below the

FIG. 6 The scheme of the Holmstedt operation, a modification of the Billroth II, shows the general principles of its technique. This is a variation of the Polya operation. In order to prevent confusion the colon is not represented in the sketch, but the loop of jejunum is brought up through a rent in the mesocolon. The upper part of the stump of the stomach is closed and the anastomosis of the jejunum is made with the lower portion of the stump of the stomach, instead of throughout its whole length.

transverse colon. The part of the loop to be anastomosed is isolated by small rubber bands which are thrust through the mesentery. These are superior to clamps and are less in the way. An interrupted suture of silk or linen is passed from the upper surface of the side of the jejunum, about halfway between the mesenteric and the convex border to the left portion of the posterior surface of the esophagus. The ends are left long. A similar suture is inserted between the right border of the esophagus and the jejunum, leaving space of about $1\frac{1}{2}$ to $1\frac{3}{4}$ inches (4 to 4.5 cm) between the two sutures (Fig. 7). While these tractor sutures are held taut, a continuous suture of silk or linen unites the jejunum to the posterior wall of the esophagus. One end of the tractor suture may be utilized for this suture. The suction apparatus is disconnected from the catheter after the stomach has been thoroughly emptied, and a transverse incision is made in the posterior wall of the esophagus beginning on the right side. An incision is made in the jejunum about $\frac{3}{4}$ inch (0.6 cm) from the suture line. The esophagus and jejunum should be thoroughly packed around with moist gauze before the sutures are placed and

as soon as the opening into the esophagus and the jejunum is made the suction apparatus is applied. Beginning on the right side a linen or silk suture in a small curved needle unites the posterior margin of the incision in the jejunum to the posterior margin of the incision in the esophagus. The suturing is then continued until the left border of the esophagus and the left extremity of the incision in the jejunum have been reached. The incision in the esophagus is carried anteriorly, catching the margin of the esophagus as it is cut in order to prevent retraction. The suture is continued around anteriorly, uniting the anterior margin of the wound in the esophagus to the anterior margin of the wound in the jejunum. As far as possible it is well to apply this suture from within, drawing the suture snugly as it emerges from the inner surface of the esophagus, as has been described in the operation for partial gastrectomy. The suture is tied to its original end, on the right side. The ends of the tractor sutures are cut short.

The first row of sutures is again taken up and carried anteriorly as a continuous suture, burying the inner row and is tied to its original end. Over this is placed a series of interrupted mattress sutures, preferably of No. 00 tanned or chromic catgut to give further strength to the union, and particularly reinforcing the two lateral borders. If any available peritoneal covered fat is found it should be brought over and caught with the long ends of these mattress sutures.

Instead of closing the stump of the duodenum, the right half of the jejunal loop is brought over and sutured to the stump of the duodenum end-to-side. By this procedure several things are accomplished. Once I lost a patient after a total gastrectomy because of a volvulus in the loop of jejunum that extended from the entero-anastomosis to the esophagus. By fixing the jejunum to the duodenum this accident can be avoided. Second, the duodenal contents can readily drain into this loop if there happens to be some blockage lower down. Third, a duodenal fistula is less liable to occur with the easy emptying of the duodenum (Fig. 7B).

At a point just below the transverse colon an entero-anastomosis is made between the two loops of jejunum and about 6 inches farther down a medium sized soft rubber catheter which has been passed through a stab wound to the left of the abdominal incision is introduced obliquely into the jejunum for feeding; this is done according to the method of Witzel, or better according to a modification of the Coffey principle.

Fig 7 Total gastrectomy. The stomach has been severed from all of its attachments except the oesophagus, and a catheter has been inserted in order to keep the stomach empty. Following the suggestion of Mayo-Robson, the stomach is turned up out of the upper portion of the abdominal wound onto the chest, and is used as a handle for exposing the oesophagus. Tractor sutures of silk or linen are inserted at each border of the oesophagus, and the jejunum and the oesophagus are united with a continuous suture of silk or linen. Coproctasis of the jejunum is provided by narrow rubber bands thrust through the mesentery. The dotted lines indicate where the incision will be made into the oesophagus and into the jejunum. Insert A shows the rubber catheter in position. Insert B shows the anastomosis of the oesophagus and jejunum, the union of the stump of the duodenum to the jejunum, and the entero-anastomosis.

Owing partly to the extensive manipulation and to the multiple openings in the bowel, and to the exposure of the oesophageal lumen, infection is much more likely to occur following this procedure than in partial gastrectomy, where drainage is rarely if ever needed. Through a stab wound in the left loin a long medium sized soft rubber drainage tube with several additional perforations is carried up to the cavity left by removing the cardiac end of the stomach. This tube fixed by suture to the skin, should not be in contact with the line of sutures but about an inch from it.

This operation is rather prolonged but by using continuous intravenous injection of dextrose in Ringer's solution and giving a transfusion of blood after the operation, shock can be combated.

Fig 8 The Devine operation. The stomach has been divided between the two clamps, one of which has been thrust through the rent in the mesocolon. The distal stump of the stomach is closed, and the proximal end united to the jejunum after the manner of a Pólya operation. It is then, if possible, drawn down through the rent in the mesocolon.

PALLIATIVE OPERATIONS

Not infrequently a large fungating tumor of the stomach, which is often a colloid cancer, will give a better prospect for cure than a small cancer which ulcerates and metastasizes quickly. Dr W J Mayo's apt remark that cancer *coming to you* is less malignant than cancer *going from you*, is real wisdom. However, these large cancerous masses may be found so adherent and extensive around the pylorus as to defy any reasonable effort at resection. When this is the case a type of palliative operation such as that suggested by Devine of Australia for certain lesions in the pyloric end of the stomach and a modification of which has been used by Pack of the Memorial Hospital in New York for pyloric cancer may be adopted. This operation seems to have all of the advantages and none of the disadvantages of gastro-enterostomy. Clamps on the stomach are placed the clamp on the oral side being inserted through a rent in the mesocolon. The stomach is severed between clamps, preferably with the cautery, about the middle of the body of the stomach, leaving ample margin for infolding the pyloric stump. The cardiac end is brought down

through the rent in the mesocolon and is sutured to the jejunum somewhat after the manner of a gastro-enterostomy (Fig. 8). Or as Pack does, both ends of the stomach may be closed and then a posterior gastro-enterostomy made. If this cannot be done, the jejunum may be united to the stomach in front of the transverse colon and an entero-anastomosis made lower down. In this way the diseased mass at the pylorus is shunted off from the course of the food and given complete rest. In the instances in which the mass proves to be not malignant, permanent recovery may be expected, but even when cancerous the growth of the neoplasm is to some extent retarded by the rest afforded the tissue, and a ready emptying of the stomach is secured.

As has been mentioned gastro-enterostomy has little if any place in the surgical therapy of gastric cancer.

In cancer of the cardiac portion of the stomach, where obstruction to swallowing is produced a gastrostomy according to the method of Janeway in which a strip from the anterior wall of the stomach with its base at the greater curvature is made into a tube for the gastrostomy is a good procedure. For a permanent gastrostomy this operation is superior to the oblique implantation of a tube according to the Witzel method, because it leaves a channel lined with mucosa which is not only more comfortable and more readily controlled, but which may be dilated and through which by means of a cystoscope radon implants can be inserted into the growth present in the stomach.

CONCLUSION

We have, then, operations applicable to the cure or to the relief of cancer wherever it occurs in the stomach. As the majority of cancers are in the pyloric portion and in the adjoining part of the body of the stomach, extirpation by the modification of the Billroth I described can often be done, or if this is inapplicable some form of the Billroth II may be used. When the cardiac portion is involved or when the stomach is extensively diseased, a total gastrectomy may occasionally be done. In inoperable conditions with obstruction, the operation of Devine when the cancer is in the pyloric end, or a gastrostomy according to the Janeway technique when the occlusion is at the cardiac end, may be used. With an accurate diagnosis and a skillful execution of these operations, many lives can doubtless be saved that are now given up as hopeless. Naturally stomach surgery requires training and experience and it will be found that with increasing experience cases that formerly were condemned as hopeless may sometimes be salvaged. This, of course, may mean a mounting rate of operative mortality, but it will also mean an increased total number of cures and a larger number of cases that can be considered resectable.

RADIUM THERAPY OF CARCINOMA OF THE CERVIX UTERI

THE STANDARD TREATMENT IN USE IN THE CANCER CLINIC OF THE WOMAN'S HOSPITAL, NEW YORK, AND A COMBINED STATISTICAL REPORT OF FIVE AND TEN YEAR RESULTS SERIES 1919-1929¹

GEORGE GRAY WARD M.D. F.A.C.S., AND NELSON B. SACKETT M.D. F.A.C.S. NEW YORK, NEW YORK

SINCE we commenced to treat cancer of the cervix with radium in 1919, we have published our 5 year results in 1925, 1928, 1930 and 1932. We have now completed 2 more 5 year series, or 10 series in 15 years, and are reporting our combined results.

As our experience increases we feel that a 10 year observation period gives us a more accurate evaluation of the curability of cancer by radiation therapy than the 5 year standard; therefore we are including in this report our 10 year results as well.

The standard technique we employ has been practically stabilized since 1920, the essential features are as follows. The preliminary building up of the patient's resistance when indicated in cachectic cases is accomplished by giving a blood transfusion if possible, as suggested by Farrar, spinal anesthesia is employed (half dose only is necessary) instead of a general anesthetic when there is no contra indication. We believe anesthesia of some sort is necessary for accurate diagnosis and biopsy, and for the correct application of the radium in most cases. We give an initial dosage of 3,600 to 4,200 milligram hours of radium, depending on the extent and size of the cancerous growth. One hundred milligrams are placed intracervically with the equivalent of 1 millimeter of platinum screening, and in the periphery at the junction of the cervix with the vaginal fornices platinum needles (0.5 millimeter) containing 12½ to 13 milligrams each are inserted, or if the vaginal vault is invaded, 75 milligrams of radium in silver boxes are used in a spring colpostat similar in principle to that of Regaud.

In exceptional cases of extensive disease we have used from 6,000 to 6,700 milligram hours for the initial dose. Since 1930 high voltage X-ray therapy has been employed by Dr. McIntosh who is in charge of our X-ray Department according to the following technique in Class III and IV cases. Two series 6 to 8 weeks apart, 4 portals 800 r per portal, at 200 kilovolts 30 milliamperes, 50 centimeter distance 0.5 centimeter copper and 1 centimeter aluminum filter. The size of portals varies with the patient and the extent of disease. Occasionally a third series has been given.

Since June, 1933, we have been using the fractional treatment whenever it has been feasible to have continued control and co-operation of the patient. The same factors of milliamperage, filter and voltage are used, the distance is increased to 70 centimeters and a fractional distribution of dosage is given as follows. Two portals are treated daily on the same side anteriorly and posteriorly, each side of pelvis; therefore, receiving treatment every other day. Two hundred r is given to one anterior and one posterior portal daily until all portals have received 2,000 to 2,400 r each. Occasionally 250 r per portal is given. The exact amount and speed of administration are judged in each individual case. This treatment takes from 3 to 3½ weeks and is not ordinarily repeated.

We are in accord with Dr. McIntosh's belief that this fractional method gives greater promise of success, and is preferable whenever possible in spite of its economic disadvantages. In cases with extensive disease we have lately been following the practice of Healy and others of preceding the radium application with the X-ray therapy.

Potassium permanganate douches and an elevated posture to promote drainage and separation of any slough are begun at once. In cases where there is an exuberant cauliflower mass protruding into the vagina, we remove it with the high frequency knife before applying the radium. Biopsies are all done with the same instrument.

We stress the importance of distance screening by distending the vagina with gauze to its capacity to keep the bladder and rectum as far away as possible from the radium rays, and we use a self retaining catheter to keep the bladder collapsed during the radium application. We believe that anchoring the radium tube in the uterus is an important detail.

The outstanding feature of our method, however, is the frequent follow up inspection made by the surgeon himself throughout the 5 year period if at all possible. During the first 3 years a monthly inspection is made, and after that the patient is seen every 2 or 3 months. If the follow up examination discloses evidence of a beginning recurrence in the vaginal walls or fornices a further irradiation is given in time to check the recur-

rence in its incapacity. Our employment of repeated irradiations after the initial treatment is for metastatic outbreaks or residuals in the vagina and consists of a relatively small dosage, usually in the form of platinum needles, although should the nature of the recurrence require it we use tubes or flat containers. The average dose ranges from 300 to 1,200 milligram hours, depending on the size and location of the recurrence. We attribute our success in saving some cases to the early discovery of a metastasis, occurring 2, 3 and 4 years or longer after the initial treatment. The value of a personal follow-up each month we believe cannot be overestimated. In no other way can we detect early recurrences long before the patient has subjective symptoms.

We have been criticized for this practice of repeated irradiation, but we believe criticism is due to a misunderstanding as to our method. We are not employing repeated applications of a heavy dosage at the initial site of the disease. We appreciate that over radiation of radioresistant tissues may result in necrosis and fistulae and late radium reactions. We are of course, in agreement with the belief that the surviving cancer cells become more radioresistant after the initial irradiation, and that therefore the initial dose should be the maximum consistent with safety. Our initial dosage approximates that used in the leading clinics.

TABLE II.—FIVE YEAR END-RESULTS IN CARCINOMA OF CERVIX. PATIENTS SEEN IN TWO YEARS FROM MAY 15 1927 TO MAY 15 1929

Total	18	98	4	16—44 (absolute rate)	(1%)

Relative five year survival 37.1%

Comparison of results by classes with other clinics must of necessity be only approximate due to the personal equation in estimating the extent of the disease. Heyman gave a well known example of this when three experienced gynecologists, visiting him in Stockholm, all classed a case differently as to the extent of the cancer. (The author Ward, was one of the three.) How often has it happened that an apparently early case with mobile uterus has been found at operation to have an invasion of the parametrium and glands?

It is our opinion that the simplest form of classification of the extent of the disease is the most useful for comparisons. Therefore we prefer Schmitz's, which we understand is used in this country by the majority of clinics.¹ The League of Nations classification is too complex to be practical in our belief and comparisons with other clinics are more open to error. However we use both systems for statistical purposes.

We believe that if cases were classified simply as "early" or "late" depending upon whether the disease has spread beyond the cervix, there would be less confusion and more accurate comparisons.

It is not correct, we think, to group League of Nations Class I and II cases together as "early" cases as Crossen has done since the League of Nations Class II includes a large number of Schmitz Class III cases which are not "early" but already have the disease extending into the parametria and vagina, but are nevertheless League

An inquiry made by us in October, 1932, of 1 of the leading clinics in the United States showed the 1st among the Schmitz classification, 3 of these was the League of Nations, only 30 among the League of Nations classification alone. Two use personal classification.

Radium operability 95.2 per cent

of Nations Class II because "the uterus still maintains some degree of mobility. The League of Nations Class II corresponds to an early Schmitz Class III in our opinion. Our cases with the disease limited to the cervix according to Schmitz's classification show Class I 2 per cent, Class II 18.6 per cent, or 20.6 per cent for our early group—not 60 per cent as has been stated.

As accurate classification of the extent of the disease must of necessity be difficult and will always be variable as the judgment of different observers varies, therefore comparisons where complicated systems are employed are of doubtful accuracy. We believe with Stoekel Mikulicz, Heyman and many others that only the absolute survival rate of an entire series is dependable for purposes of comparison.

As to our use of re radiation of recurrences in the vaginal tract, the following case seen recently is an example of our procedure.

Mrs. R. came to the clinic with a Class III adenocarcinoma of the cervix invading the vaginal vault. She was given 6,000 milligram hours at the initial treatment in the uterus and vaginal vault. This was followed with two series of high voltage X ray therapy. The result was apparently entire disappearance of the disease, with perfect healing. Six months later the patient felt well and was without symptoms, but at the monthly inspection a metastatic nodule, the size of a large pea, which bled to touch, biopsy positive, was found just inside the introitus on the right vaginal wall. This was promptly re radiated with radium needles.

We would ask our critics, what would they do under such circumstances?

Heyman in an address before the Royal Society of Medicine in 1929, stated "We have in recent years in cases of persistent small residua and in cases of smaller vaginal recurrences made use of intubation of radium needles. We do likewise

TABLE VI—AGE DISTRIBUTION IN CARCINOMA OF CERVIX

Years	Number	Per cent of total
20-29	11	2.4
30-39	90	19.7
40-49	125	27.3
50-59	149	32.6
60-69	50	10.9
70-79	13	2.9
80-89	9	2.0
Total	457	100.0

Youngest—24 years

Oldest—81 years

4.6% of the patients were under 30 years of age.

TABLE VII—PRIMARY MORTALITY OF RADIUM TREATMENT FOR CARCINOMA OF CERVIX

	Cases treated with radium	Radium applied cases	Deaths	Deaths per 100 applied as	Deaths per 100 cases
Total, all classes to date	576	595	10	1.6	1.6
Class I Schmitz (Stage I, Class II Schmitz) L. of N.	16	2	0	0	0
Class III Schmitz (Stages II & III, L. of N.)	116	81	0	0.54	0.86
Class IV Schmitz (Stage IV L. of N.)	463	748	5	0.66	1.1
Class V Schmitz (Stage V L. of N.)	29	43	4	0.3	3.8
Class V Schmitz (Stage V L. of N.)	3	3	0	0	0

rather than not give the patient a chance and our results in many cases seem to justify this practice.

From February 15, 1919 to May 15, 1934, we have had under our care 657 cases of carcinoma of the cervix, 630 of which have been treated with radiation therapy. 27 were left untreated since the disease was too far advanced. Including the new 1928 and 1929 series we now have 457 cases in which the 5 year observation period has been completed to May 15, 1934.

The complete statistics are shown in the following tables.

Table I shows the 5 year survival rate of all cases seen from 1919 to 1929 inclusive.

Table II shows the 5 year end results in the last two series 1927-29.

Table III gives the 10 year end results from 1919 to 1924. This table shows that more than two-thirds of the patients surviving 5 years have lived 10 years or longer in spite of the lowered life expectancy of their respective age groups.

The untreated cases were, in our judgment, too far advanced for treatment (Table V).

Table VII shows that many Class IV cases probably should not have been treated.

TABLE VIII.—CARCINOMA OF CERVIX FOLLOWING SUPRAVAGINAL HYSTERECTOMY

	Number	Per cent
Total cases seen	477	
Postoperative stump	17	3.59
Living 5 years	11	
Absolute survival		46.7

TABLE IX.—FIVE YEAR END-RESULTS ACCORDING TO EXTENT OF DISEASE. SCHMITZ CLASSIFICATION OF CARCINOMA OF CERVIX CASES

Class	Total seen	Treated	Un-treated	Living 5 years	Absolute survival per cent	Relative survival per cent	1st & 2nd rel. to 1st
I	6	6		6	66.6	66.6	100
II	61	61		30	30	30	100
III	177	177		61	34.4	34.4	100
IV	28	28	8				100
Total	172	172	8	97	55.8	55.8	

It is to be noted that this table shows that "early" cases Class I and II had an absolute and relative survival rate of 51 per cent and the "late" cases Class III and IV had an absolute survival rate of 1 per cent and a relative rate of 1 per cent.

Table VII excludes 107 cases with previous or subsequent treatment or operation elsewhere, or treated previous to May 1920, when method was unstandardized.

Our results have been obtained during a period in which our X-ray therapy was inadequate, judged according to modern practice. Our series from 1920 therefore should show an improved survival rate.

SUMMARY

During 15 years at the Woman's Hospital we have had under our observation for 5 years or longer 457 cases of carcinoma of the cervix, 410 of whom have been treated with radium.

These 10 five year series have a relative (treated) survival rate, 5 years or longer of 55.8 per cent and an absolute survival rate (all cases seen) of 47.9 per cent with a completed follow up of 9.04 per cent. All untreated cases are classed as dead of cancer. "Early" cases showed 55.8 per cent survival.

Two hundred and eight cases have been observed for 10 years or longer and have a relative survival rate of 18.31 per cent and an absolute rate of 1.9 per cent. This shows that more than two-thirds of the cases that survived 5 years lived 10 years or longer in spite of the normal death expectancy in the various age groups.

TABLE X.—FIVE YEAR END-RESULTS ACCORDING TO EXTENT OF DISEASE. LEAGUE OF NATIONS CLASSIFICATION OF CARCINOMA OF CERVIX CASES

Stage	Total seen	Treated	Un-treated	Living 5 years	Absolute survival per cent	Relative survival per cent
I	64	64		3	4.7	4.7
II	179	179		46	25.7	25.7
III	28	28		16	57.1	57.1
IV	28	28	11			
Total	179	179	11	115	64.2	64.2

IV	IV			11			

TABLE VII.—FIVE YEAR END-RESULTS IN CARCINOMA OF CERVIX TREATED BY UNIFORM WOMAN'S HOSPITAL RADIIUM TECHNIQUE (COMPARE WITH TABLE I)

	Total seen	Treated	Un-treated	Living 5 years	Absolute survival per cent	Relative survival per cent
Total	379	379	5	114	29.8	29.8
Cases I & II Schmitz stage I & II, limited to one	11	11	1	11	100	100
Cases III & IV Schmitz stage III & IV, limited to one	178	178	1	11	6.2	6.2

*The figures in parentheses are of Table I.

A frequent personal follow up of all cases throughout the 5 year period of observation is essential if we are to discover early metastatic recurrences or recidiva in the vaginal tract before subjective symptoms develop, and in time to arrest the recurrence.

Re-radiations of this character are of definite curative or palliative value in many cases.

The classification of the extent of the disease should be simplified to the utmost degree to make comparisons with other clinics of value.

The classification of Schmitz is less complicated than that of the League of Nations, and we believe is in more general use in this country.

The absolute-cure rate of all cases applying for treatment, in our opinion, is the only criterion of value in comparing methods of therapy.

The frequent personal follow-up inspection made by the surgeon himself throughout the 5 year period of observation will not only result in fewer untraced cases and therefore improve his absolute survival rate, but it will also enable him to save more patients.

UNILATERAL CARCINOMA OF THE BREAST TREATED BY SURGICAL OPERATION AND RADIATION¹

STUART W. HARRINGTON M.D., F.A.C.S. ROCHESTER, MINNESOTA

Division of Surgery Mayo Clinic

MANY theories have been advanced to explain the etiology of carcinoma of the breast, but none has been proved. The most generally accepted opinion as to the course of the disease is that it begins as a localized lesion and is disseminated to other parts of the body by way of the lymph stream and occasionally by the blood stream. It is on this conception of the disease that its treatment by surgical operation is based with a view to complete eradication of the disease. The possibility of accomplishing this objective depends on the extent of the disease at the time of operation and the type of surgical procedure instituted. The effectiveness of surgical treatment is indicated by the results obtained. The surgical results may be influenced by the use of roentgen rays and the effectiveness of the roentgenological treatment depends, to some extent, on the degree of malignancy.

The surgical procedure most generally accepted for the treatment of carcinoma of the breast is radical amputation, the fundamental principles of which were set forward by Halsted and by Willy Meyer, working independently, in 1888. There was an epochal contribution to the treatment of carcinoma of the breast, for since their publications surgical treatment has been the most effective method of combating the disease.

RADICAL AMPUTATION

The technique of the primary radical amputation has been fairly well standardized. I do not make a uniform type of incision in the skin for I believe that the best results are obtained when the incision is planned in each case so as to remove the greatest amount of skin around the region of

the growth, and to leave the least deformity and the least restriction of motion of the arm. If the incision is properly planned, in accordance with the situation of the tumor, sufficient skin can be removed so that there is little danger of local recurrence, and skin grafting is rarely necessary except when the lesions are most extensive. In general, if the tumor is in the upper or lower quadrant of the breast, a vertical incision will give the best results in the way of complete removal of the growth and adequate exposure for deep dissection. If the growth is in the extreme inner or outer quadrant of the breast, a transverse incision is usually best.

After the incisions in the skin have been outlined, the subcutaneous tissue is dissected around the entire operative field, the median portion of the dissection being carried to the median line, the lateral portion is carried to the border of the latissimus dorsi muscle, extending below to include the tissue over the upper portion of the fascia of the rectus muscle and extending above to the clavicle. Approximately two-thirds of the clavicular portion of the pectoralis major muscle is then divided, and its attachment is severed from the humerus. The lymph nodes along the upper portion of the brachial vessels are thoroughly removed, and the dissection is carried to the lower border of the pectoralis minor muscle. The attachment of this muscle to the coracoid process of the scapula is severed. The dissection of the axillary and sternal lymph nodes is completed, and all of the nodes are removed along the lateral wall of the thorax, along the axilla, both above and below the axillary vessels, to the entrance of the axillary vein into the thoracic wall. The branches of the axillary vessels

vessels are caught and ligated as the dissection of the lymph nodes proceeds toward the sternum the long thoracic and subscapular nerves are preserved. This completely outlines the tissues to be removed which are still attached to the wall of the thorax they include the breast, subcutaneous tissue, axillary nodes and node bearing fascia, the pectoralis minor muscle, and the greater portion of the pectoralis major muscle. These structures are then dissected from the wall of the thorax, starting from the lateral aspect the perforating intercostal vessels are ligated as the dissection proceeds. The anterior sheath of the rectus muscle is removed as the dissection proceeds toward the median line, and the entire carcinomatous portion is removed in one mass.

From the standpoint of operative procedure, the best results from surgical treatment of carcinoma of the breast are obtained from primary radical amputation. There are many variations in methods of carrying out the minor details of the radical amputation but the fundamental principles of the operation are invariable and should be carried out in all cases accepted for surgical treatment. This initial treatment is by far the most important procedure and the possibility of a cure depends on the thoroughness with which it is carried out. The importance of this cannot be overestimated, for secondary operative procedures are rarely curative. I believe that one of the important factors in the unsatisfactory results obtained from surgical treatment is the relative frequency with which minor operative procedures are carried out for malignant disease. The most unsatisfactory results from surgical treatment are obtained from secondary radical amputations, following a previous minor operative procedure. Approximately 7 per cent of our radical amputations at the Mayo Clinic have been secondary procedures of this type. In this group lymphatic involvement had occurred in 79 per cent of cases, as compared with 64 per cent in which primary radical amputation had been done. The results of the secondary radical amputation are correspondingly less satisfactory. These figures, however, do not give the true results in those cases in which a primary minor operative procedure had been done because in approximately 60 per cent of these the condition was hopelessly inoperable at the time the patients presented themselves for examination. This is particularly true of cases in which some type of escharotic had been used among these cases more than 80 per cent were inoperable at the time of our examination.

TWO TYPES OF CASES

From the surgical standpoint, lesions of the breast may be grouped in two classes first, the group in which a clinical diagnosis of malignancy can be definitely established and a primary radical amputation can be done immediately and second, the group in which the diagnosis cannot be definitely established on the basis of clinical manifestations of the disease.

In those cases in which a definite clinical diagnosis can be made, the disease is usually fairly well advanced and immediate, primary radical amputation is indicated. Inasmuch as one of the most important factors in the results of operation is the extent of the disease at the time of operation, the results will depend on the extent of the lesions of patients who are accepted for operation. Statistical studies on the results of operation are often misleading and do not give the true conception of the results obtained, unless it is known where the line is drawn between operable and inoperable growths. If only small lesions without demonstrable axillary metastasis should be considered acceptable for surgical treatment, the statistical results would be very satisfactory. This, however, would include only a relatively small number of patients, for the majority of patients present fairly well advanced lesions at the time of their initial examination. In most cases, the lesions are more extensive. Many patients present ulcerated lesions of the breast and metastasis to axillary lymph nodes. Radical surgical treatment cannot be expected to effect cure in these cases but in many instances can give comfort and additional life and I believe the patients deserve the benefit of surgical treatment.

There are varied opinions as to what constitutes an operable condition. I shall state briefly the criteria of operability followed in this series. Any lesion of the breast was considered operable if it was freely movable from the thoracic wall, regardless of ulceration and in some cases even if there were cutaneous nodules proximal to the tumor. The condition was considered operable regardless of the presence or absence of palpable axillary lymph nodes and in some cases in which supraclavicular nodes were palpable and were confined to one side of the neck the condition was considered operable. Patients were also accepted for operation if they presented the diffuse type of malignant disease, so called inflammatory malignancy or if the breasts were in a state of lactation, or in most cases, if patients were pregnant. The condition was considered inoperable if there was a large growth fixed to the thoracic wall and if there was extensive metastasis to the regional

TABLE I.—FIVE YEAR RESULTS COMPARISON OF CASES IN WHICH AXILLARY INVOLVEMENT WAS PRESENT WITH CASES IN WHICH IT WAS NOT PRESENT

	Patients operated on		Lived 5 or more years after operation	
	Total	Traced	Patients	Per cent of traced
Without axillary metastasis	1230	1086	278	77.4
With axillary nodal metastasis	30	3031	363	27.8
Total	1351	1377	310	45.7

lymph nodes or to distant parts of the body. In a few cases, in which there was distant metastasis, the patients were accepted for operation because of exceptional circumstances. It is difficult to draw any sharp line between operable and unoperable lesions, and treatment should be instituted according to the findings in each case. All patients were accepted for operation if it was thought that they had a reasonable chance of obtaining greater comfort or longer life from the surgical treatment or if there was ground for hope that the disease could be completely eradicated. It may seem that these rules which govern operability have not been drawn strictly enough, and that patients have been accepted for operation whose growths were too extensive. This is a matter of opinion, and the justification for operation is found in many cases in which the condition was thought to be absolutely hopeless before operation but in which the patients have lived and have enjoyed many years of comfort following the operation. I do not believe that the presence or absence of palpable axillary lymph nodes should be a criterion of surgical treatment, because I do not believe that it is possible definitely to ascertain whether this enlargement is the result of metastasis on clinical examination in all cases. Of cases observed in the past year palpable nodes were found in 60 per cent and in 68 per cent of these definite axillary metastasis was found at the time of operation. In the remaining cases the enlarged nodes were found to be only inflamed. In the 40 per cent of cases in which enlargement of the axillary nodes was not found clinically, axillary metastasis was present in 29 per cent. In these cases the metastatic nodes were under the pectoral muscles, and along the axillary vein, where they could not be felt on clinical examination. In view of the frequency with which these palpable nodes are found to be only inflamed on microscopic examination, I do

TABLE II.—FIVE YEAR RESULTS COMPARISON OF CASES IN WHICH OPERATION WAS PERFORMED WITH CASES IN WHICH BOTH OPERATION AND ROENTGENOLOGICAL TREATMENT WERE CARRIED OUT

	Patients operated on		Lived 5 or more years after operation	
	Total	Traced	Patients	Per cent of traced
Surgery alone without axillary metastasis	551	494	345	69.8
Surgery and radiation without axillary metastasis	640	501	437	73.8
Surgery alone with axillary metastasis	640	604	147	24.3
Surgery and radiation with axillary metastasis	1559	1447	416	28.8
Total	1351	1377	1330	45.7

not believe that surgical treatment should be refused in these cases.

The second group of cases consists of those in which a diagnosis cannot be definitely established on the basis of clinical manifestations of the disease and these cases present a more difficult problem. This is the most important group from a surgical standpoint. In a general way, the malignant lesions of the breast which do not present the characteristic signs of malignant disease clinically are usually early lesions, and the most satisfactory operative results are obtained from surgical treatment in these cases. In the indeterminate clinical cases the question may arise as to whether it is better to keep the patient under observation or to treat the condition surgically. In all cases in which there is a single localized tumor, without definite clinical signs of malignant disease, the only safe course to follow is to establish a definite diagnosis by surgical removal of the tumor for microscopic examination. The tumor should be removed by wide excision, well away from the limits of the growth, without trauma to the lesion or surrounding tissues. Usually I prefer to remove a wedge-shaped piece of tissue including the margin of the growth, and well away from it. Microscopic examination of the tumor should be made immediately after its removal, before the wound is closed. If the tumor proves to be malignant, the operation should be completed as a radical amputation, if it is benign the breast can be reconstructed with very little deformity. I do not believe that it is ever advisable to remove any growth from the breast without immediate examination of a frozen section of the tissue, the manner of completing the operation is indicated by the results of this examination.

TABLE III.—FIVE YEAR RESULTS RELATIONSHIP BETWEEN INVOLVEMENT OF AXILLARY NODES AND GRADE OF MALIGNANCY

Treatment	Grade of malignancy	With involvement of axillary nodes				Without involvement of axillary nodes			
		Patients operated on		Lived 5 or more years after operation		Patients operated on		Lived 5 or more years after operation

		772	731	60	9	55	30	33	64

RESULTS

In the accompanying tabulations, all patients operated on have been included in the surgical results, regardless of the extent of the disease at the time of operation and a high percentage of cases is included in which all that could be hoped for was palliation. The tabulations also include those cases in which a primary operative procedure had been carried out elsewhere, followed by a radical procedure at the clinic, as well as those cases in which the prognosis was influenced by other associated conditions, such as diabetes, exophthalmic goiter, pregnancy, lactation, and diffuse cancer *en castris*. It is not within the scope of this paper to discuss the results obtained, classified according to the various groups. I shall publish these in a subsequent paper.

In this paper I shall give the 5 year results obtained from radical amputation for unilateral carcinoma of the breast. I shall then compare the 5 year results obtained in those cases in which radical amputation constituted the complete treatment, with the 5 year results in cases in which roentgen therapy was administered, in addition to performance of radical amputation. I shall also compare, according to the 4 grades of malignancy the 5 year results obtained by surgical treatment only with those obtained by surgical treatment and roentgen therapy together. These results are based on all cases in which operation was performed at the clinic from January 1, 1910 to January 1, 1929, this permits the compiling of 5 year results in all cases. The cases numbered 3,381 and the results are based on 3,137 cases in which the patients were traced, or 92.64 per cent of the entire series.

In Table I are compiled the 5 year results of treatment by radical amputation. The entire series has been divided into two groups for comparison depending on the presence or absence of involvement of axillary lymph nodes at the time of operation. In Table I it is shown that the results were much better in the cases in which axillary metastasis to lymph nodes had not taken place before the time of operation. Therefore, the presence or absence of metastasis to axillary lymph nodes at the time of operation is one of the most important indications in estimating prognosis. I believe that in all studies on the results of treatment of carcinoma of the breast, division into these two main groups should be made as an initial attempt to obtain uniformity of types of cases for comparison of results.

In Table II are recorded the 5 year results obtained in cases in which radical amputation only was done, for comparison with the 5 year results obtained in cases in which radical amputation was followed or was preceded by roentgen therapy. This study shows that (as compared with similar patients who were subjected to radical amputation only) 3 per cent more patients without axillary nodal metastasis lived 5 years, who received roentgen therapy, in addition to radical surgical treatment. Among cases in which axillary nodal metastasis was present, a similar comparison disclosed that 4 per cent more patients lived 5 years, who received roentgen therapy in addition to radical surgical treatment. Whether treatment was by surgery only or by surgery and roentgen rays, the difference in the percentage of comparable patients who lived 5 years was small. By "percentages of comparable patients" I mean

to compare the following percentages in Table II 69.8 with 72.8 24.3 with 28.8. In all of the comparisons of comparable patients the percentage of those who were living at the end of 5 years was slightly higher among those who received both surgical and roentgenological treatment than among those who received only surgical treatment. It would appear, therefore, if the differences in percentages are great enough to be of any significance that the better results could be attributed to roentgenological treatment. It should be emphasized, however, that the differences with which we are dealing are small and that perhaps a larger series of cases would not show any materially better results in cases in which roentgenological therapy was added to the surgical treatment.

It is of greatest interest to subdivide each of the two main groups (the group of cases with, and the group of those without, axillary nodal metastasis) into 4 classes according to the grade of malignancy, making 8 classes in all. I believe that the comparison of the results of any type of treatment are most accurate when comparisons are made according to this classification. The grading in these cases has been done according to Broders' method of dividing malignant lesions into 4 grades, based on cellular differentiation. This part of the study is based on 2,396 cases, which are all of the cases in this group of 3,137 traced cases in which the growth has been graded. It was found that cases of grade 1 comprised 69 cases or 2.88 per cent of the total, cases of grade 2, 288 cases or 12.02 per cent of the total, cases of grade 3, 796 cases or 33.22 per cent of the total and cases of grade 4, 1,243 cases or 51.88 per cent of the total. It is shown by these percentages that in 85 per cent of cases of malignant disease of the breast, the growths were of malignancy graded 3 and 4. This is an important factor and influences the results of surgical treatment because in comparison with growths of other grades, those of high grades of malignancy are more often associated with axillary nodal metastasis at the time of operation. As is shown by a study of these 2,396 cases in which the grade of malignancy was determined, 17.4 per cent of patients whose growths were of grade 1 had axillary nodal involvement at the time of operation and the same was true of 55.9 per cent of those whose growths were of grade 2, of 79.2 per cent of those whose growths were of grade 3, and of 88.8 per cent of those whose growths were of grade 4. This study shows that the majority of the malignant lesions of the breast are of high grades of malignancy, and that these high grades

TABLE IV—COMPARISON OF LENGTH OF LIFE OF PATIENTS TREATED BY SURGERY ONLY AND BY SURGERY AND ROENTGEN RAYS

	Total patients operated on	Patients dead		Average years before death
		Number	Per cent	
Surgery alone				
No glandular involvement	527	240	45.80	5.17
With glandular involvement	649	528	81.44	2.8
Surgery and post-operative radiation				
No glandular involvement	649	216	37.90	4.22
With glandular involvement	755	702	92.45	2.5

of malignancy are most often associated with axillary nodal metastasis at the time of operation, this is one of the most important factors in prognosis.

Part of the foregoing paragraph has been derived from Table III, which was compiled as the basis of a study of 5 year results in relation to grade of malignancy. The cases were divided into 2 main groups, those in which there was axillary nodal metastasis at the time of operation and those in which axillary nodal metastasis was absent at the time of operation, and each of these main groups was divided into 4 classes according to the grade of malignancy of the growth. Comparison was then made in each of the classes between the cases in which treatment was by surgery only and those in which both surgery and radiation were used. This study shows that there was practically no difference in the results obtained in cases in which malignancy was of grade 1, whether surgery only was used, or whether both surgery and radiation were employed.

In cases in which malignancy was of grade 2 the comparison, as before, was between patients who were treated by surgery only and patients who were treated by surgery and roentgen rays. The results were rather paradoxical among patients with axillary nodal involvement, the larger number of those who lived 5 years were treated by surgery only among patients without axillary nodal involvement, the larger number of those who lived 5 years were treated by surgery and roentgen rays. To continue this comparison in cases in which malignancy was of grade 3 among patients with axillary nodal involvement the larger number of those living were treated by surgery and roentgen rays whereas among patients whose axillary lymph nodes were not involved the larger number of living patients were treated by surgery only. Now, concerning cases in which malignancy was of grade 4 among patients whose axillary nodes were affected as well as among

those whose axillary nodes were not involved, the larger number found to be living at the end of 5 years had been treated by surgery and roentgen rays.

In comparing the results in cases in which treatment was by surgery alone with those in which treatment was by surgery and radiation although the study discloses no significant difference in the results obtained, as has been said and substantiates the former study. It indicates that there may be some improvement in the results obtained in high grades of malignancy particularly if axillary nodal metastasis is associated. When treatment is by surgery and radiation and the grade of malignancy is low radiation as an adjunct to surgical treatment seems to be of no value.

This study shows that the grade of malignancy gives the most important indication as to the prognosis, for patients whose growths were of grade 1 lived the longest period of time and patients whose growths were of grade 4 lived the shortest length of time. This holds true whether or not axillary nodal metastasis was present or absent.

In Table IV is recorded a study of the patients who died of malignant disease of the breast following operation or following operation and radiation in this group of cases the complete end-results are definitely known. This study was made to determine the length of life of those patients who were treated surgically only as compared with those who were treated by surgery and roentgen rays.

This study shows that patients treated by radical surgical operation only and who presented no axillary nodal metastasis at the time of operation lived on an average of one year longer than a similar group of patients who were treated by surgery and radiation. Patients treated by radical surgical operation only and who presented axillary glandular metastasis lived approximately

6 months longer than the group of patients treated by radical surgical operation and radiation. These figures are significant and indicate that roentgen therapy is of no definite aid in radical surgical treatment of carcinoma of the breast and they also indicate that it may be detrimental to the results of surgical treatment in some cases. These figures, however, are not conclusive because a smaller percentage of patients who underwent both surgical operation and roentgen therapy were dead at the time of the compilation of these results, and as the end results are obtained on a higher percentage of these cases than this, the tendency will be to lessen the difference in length of life of patients of the two groups.

COMMENT AND CONCLUSIONS

The most efficient surgical treatment for carcinoma of the breast is primary radical amputation. The results depend on the thoroughness with which this procedure is carried out in an initial operation.

This study reveals that roentgen therapy has been of no significant aid as an adjunct to radical surgical treatment and should be used not as a routine treatment but only if the malignancy is of high grade for the 5 year results indicate that it may be of aid in cases in which malignancy is of high grade.

The end-results in cases in which the patients have died show that the patients who were subjected to surgery only lived longer than those who were subjected to both surgery and roentgen therapy. In these cases it is evident that roentgen therapy was not of aid to surgical treatment and may have been detrimental to it in some cases.

The most important factors in prognosis are the extent of the disease, as shown by the presence or absence of axillary nodal metastasis, and the degree of malignancy as shown by microscopic examination of the lesion.

STANDARD METHODS OF TREATMENT OF CANCER OF THE LIP
BY SURGERY AND RADIATION¹

ELLIS FISCHEL, M.D., F.A.C.S. St. LOUIS, MISSOURI

From the Surgical Service of the Barnard Free Skin and Cancer Hospital

WHENEVER the practice of medicine becomes static whenever the medical profession is in perfect accord in regard to the best method of handling any disease, at that moment will the art of the practice of medicine become dead. The "aliveness" of the art of the practice of medicine is nowhere more clearly demonstrated than in a consideration of the various methods advocated for the treatment of cancer of the lower lip. However, while we fully recognize the sincerity and honesty of various workers in this field we cannot consider seriously any method of treatment which does not carry with it certain logic based upon the known pathology of the disease. While there have been great changes in therapy due to the discovery, first, of X ray, later of radium with their unquestioned destructive effects upon malignant tissue, the pathology of cancer of the lip is the same today as it has always been. True, in certain clinics and among certain physicians the diagnosis of cancer of the lip may be made at an earlier stage and hence the average case which presents itself for treatment may be different from the average case of 50 or 100 years ago, yet the processes involved in the causation (whatever they may be) and the dissemination of cancer of the lip are exactly the same.

The problem of treatment involves two distinct phases first—and much the more immediately important to the patient—the treatment of the primary, visible lesion second—and equally important in a large percentage of cases—is the handling of the lymph nodes which become secondarily involved. Theoretically speaking no patient should ever die of cancer of the lower lip. The vermilion border and the mucocutaneous margin are so plainly visible to the patient, to his family and friends, that any lesion at this site ought not to escape his attention. Should the lesion start upon the mucous membrane surface on the inside of the lower lip, the patient cannot help but be aware of it in the early stages through feeling it with his tongue. Thorough destruction of the primary lesion in its early stages is such a simple matter that it should never be possible to have a recurrence. The lymph channels which drain the lower lip are so circumscribed, so constant, so accessible, and the lymph nodes into which they empty are likewise so constant in their

distribution and so accessible, that the problem of metastases is also a comparatively simple one. Yet cancer of the lip still exacts a considerable annual toll in human life, and because of an improper understanding of the disease or faulty treatment, many patients must undergo severe pain or mutilation or both in order that the physician may obtain a result which could have been obtained in the incipient stage of the disease by a comparatively insignificant procedure.

In the handling of a considerable number of cases of any disease the physician consciously or unconsciously divides the cases into different groups, each of which is handled according to more or less rigid rules. In the treatment of cancer of the lower lip certain standards can be evolved. These standards should be determined by the extent of the disease, the location upon the lip, the general condition of the patient (including his psychological reaction to his disease), the available facilities for treatment and the histopathology of the lesion. In regard to primary cancer of the lip one can say that any method which completely destroys the tissue that contains cancer is permissible. It has been shown beyond controversy that radiation when properly employed either by X ray or radium will effectually destroy the primary lesion. It has likewise been shown that surgical excision, either with the scalpel or the high frequency cutting current, can effectually remove the invaded tissue of the lip. These facts are so well recognized that I shall only briefly enumerate the relative advantages and disadvantages of each method. Radiation destroys cancer, in all probability, by direct action upon the cancer cells (which are less resistant to the destructive action of radiation than normal tissue cells) plus such a degree of alteration of the normal tissue in which the cancer cell lies that life for the cancer cell becomes impossible although life of the normal tissue cell, while changed, still goes on. This difference between the viability of the cancer cell and the normal tissue cell makes it possible, with radiation, to destroy cancer of the lower lip with a minimum of loss of normal tissue and hence minimal deformity. With surgery this difference in viability is not a factor and the effectiveness of treatment depends upon absolute removal of all the normal

Fig. 1 First case at Barnard Free Skin and Cancer Hospital of carcinoma of lower lip treated by radiation from radium, February, 1918. Neck dissection 3 months after treatment of lip. Patient still living free of evidence of carcinoma.

Fig. 2 A, Satisfactory result can confidently be expected from proper use of radium. Neck dissection indicated regardless of histology of tumor. B, Lip healed. Suprathyoid dissection complete. Patient well 7 years later.

tissue in which the cancer may lie as well as the actively involved cancer tissue. This necessarily results in loss of much normal tissue. Radiation can be administered without hospitalization and without loss of the patient's time from business or social activities. Surgical removal on the other hand, although not necessarily disabling to the patient, will usually require some loss of time and sometimes hospitalization. Discomfort to the patient from radiation is most variable. Rarely will a patient go through the subsequent reaction without some inconvenience or pain. In surgery pain and discomfort are not great; they occur almost immediately and last a comparatively short time as compared to the long drawn-out healing from radiation. Hence in the average case it will be seen that there is not a great deal of choice. For my own part, it is my practice to excise with the scalpel lesions up to one centimeter in diameter by means of V excision. Lesions larger than this are treated by radiation with radium. This general rule does not apply to lesions of the

mucous membrane, particularly at or near either angle of the mouth. I regard these lesions as distinctly of more serious import than lesions of the vermilion border or of the mucocutaneous junction. Such lesions are treated with wide surgical excision and immediate repair of the resultant defect by utilization of tissue from the upper lip.

It is difficult to lay down hard and fast rules for radium therapy because, in different clinics, the quantity of radium available, type of applicators and type of ray employed are subject to such wide variation. But some rules should be standard. First, the area to be irradiated should comprise a great deal more than the visible or palpable margins of the growth. Second, the estimated "dose" should be given in one sitting or within a limited time. Third, if the estimated dose (and dosage should be overemphasized rather than underestimated) has failed to cause complete retrogression, radiation should not be persisted in. It is well to remember that tissue irradiated to the point of destruction of cancer is not favorable tissue for

Fig 3. Almost identical case to Figure 2. Prophylactic neck dissection repeatedly urged and refused until large "boil-like" metastasis appeared in submental region. Neck dissection too late. Patient died 2 years after first consultation.

kindly wound healing should surgical excision of recurrence or plastic repair of defects become advisable. On the other hand, should surgical excision of the primary lesion be the method of choice for the first attempt at eradication and should recurrences appear, radiation may be employed without regard to the operative wound, always with the reservation, however, that any scar tissue is apt to react unfavorably to radiation. Also, let me sound a warning—no one has the right to undertake the treatment of cancer of the lower lip with the idea in mind that if one method of treatment fails another may be tried. He who first treats the condition has the golden opportunity. If he fails to obtain a cure

the patient's chances are reduced at least 50 per cent irrespective of the subsequent method of treatment.

Discussion of the topic of treatment for the second phase of the disease, namely, treatment of the regions of lymphatic involvement by metastases, develops a veritable battleground of divergent opinions. The theory of radiation in the treatment of cancer in the lymphatic system is based upon the power of either roentgen- or radium rays to penetrate the skin and to impinge themselves upon the cancer cell with enough destructive energy to kill it. There is another theory that through radiation the lymphatic channels are blocked so that the cancer cell cannot

Fig. 4

of lymph-bearing area in every case.

Fig 6. Lip "blown out" in fashion by radiation. Repair very difficult due to devitalization of normal tissue. Note metastasis in submaxillary region which did not respond to interstitial radiation. (Am. J. Surg. 1934, 24 No. 3.)

Fig. 7 Example of possibilities of successful surgery in advanced case. Repair satisfactory from cosmetic and functional viewpoints.

wander through these channels. Still a third theory is that radiation is effective through its power to cause a marked thickening of the capsule of a lymph node in which cancer may be to such an extent that even though the cancer cell may live, it cannot grow through this capsule. The great drawback to the practical application of these theories is the undisputed fact that radiation does not have the same effect upon all cancer cells and neither does all normal tissue react similarly to radiation. The most telling observation to be made in regard to the practice of radiation therapy in the treatment of possible metastases from cancer is that the so called prophylactic radiation therapy is given with a great deal less intensity than when radiation is employed as a possible curative agent when metastases are definitely present. The logic of this common practice is to me obviously fallacious.

There was a time in the first twenty years of radiation therapy when the radiologist received for treatment only such cases as were not accept-

able to the surgeon. Now the pendulum has swung in the other direction and the surgeon is seeing more and more the patient who has passed through the hands of the radiologist and comes to him in the hope that something can still be done after radiation has failed.

The surgical removal of the subcutaneous lymph-bearing tissue which immediately drains the lower lip is an anatomical feat which involves the absolute removal from the body of a certain amount of tissue in all cases. The lymph channels from the lower lip are unusually constant and the lymph nodes into which they drain are located above the hyoid bone and extend from the lower one-third of one parotid gland to the other. Primary metastases to more distant nodes are exceedingly rare as are, also, metastases to the lungs, mediastinum or more distant parts of the body. Contrary to some writers on this subject, I have found crossed metastases of frequent enough occurrence to justify bilateral removal of tissue in all cases regardless of the location of the

Fig. 8 Example of possibilities of interstitial radiation. Patient's general condition did not warrant radical surgery. Patient barely survived pain and toxicosis accompanying slow destruction by use of radium. Plastic repair was very difficult due to devitalized normal tissue which bor-

dered upon the defect. Final result was a water tight mouth, but a poor cosmetic appearance. Patient died 5 years after treatment. Autopsy disclosed bronchiectasis, but no evidence of carcinoma. (*Am. J. Cancer* 1937, 35, No. 3.)

primary lesion. The operation is performed in the same manner whether or not lymph nodes are palpable. The only qualification of this statement is that should metastases be proved in certain groups of lymph nodes it is recognized that the disease has probably gone beyond the area of initial operation and an extended surgical interference is indicated. This procedure is entirely logical as it concerns itself purely with the pathology of the disease. Its disadvantages are manifest, inasmuch as it subjects the patient to a major surgical procedure which in a certain proportion of cases will be unnecessary, since all cases of cancer of the lower lip do not form metastases.

Naturally such an operation should not be advocated for a patient who is a poor surgical risk with an estimated life expectancy of 3 years or less. But the number of patients who present themselves, 3 to 5 years or longer after the lip has healed with advanced metastases to the cervical nodes has caused me to believe that to heal the lip lesion without removal of the immediately draining lymphatic area is just as great a mistake as for instance to remove the breast for cancer and let the axillary lymph nodes remain behind untouched.

Undoubtedly the ideal surgical treatment of cancer anywhere in the body is a one stage operation which removes the primary lesion and the regional lymphatic system at one time. This ideal can be attained in cancer of the lower lip. Stewart in 1909 advocated and described such an operation. It is to be recommended for the treatment of cancer recurrent after any form of treatment and in cancer of the mucous membrane surface of the lip. But since radiation in any stage of the disease and V excision for the small lesion has proved of such value in the treatment of the primary lesion, treatment has logically fallen into the two stages already described.

Fig. 9. Result following Stewart operation for small lesion on mucous membrane surface

But when should the second stage be performed? As yet we have no reliable data upon which to base an estimate as to the time at which metastasis occurs. The assumption that palpable nodes in the presence of demonstrable primary cancer means metastases in these nodes has been proved erroneous. In a recent study of this question of metastases from cancer of the lip the writer found that of 42 cases with palpable nodes 28 were diagnosed hyperplastic and 14 carcinomatous on microscopic examination. In 13 cases the records showed definitely that the nodes were not palpable yet in 2 of these 13 cases carcinoma was found on microscopic study. It is manifest that the clinical evidence of metastases, in a large proportion of cases, is entirely unreliable.

Obviously it cannot be considered logical to subject a patient to the surgical attack on the lymph channels unless it is reasonably certain that his primary lesion is healed. For a number of years I have adopted the following rather arbitrary practice in regard to time of removal of lymph nodes after radiation of the primary lesion. If there are no lymph nodes palpable at the time of treatment of the primary lesion wait 3 months (local recurrences following radiation will usu-

Fig. 10. Result following Stewart operation for extensive lesion lower lip. Entire lower lip reconstructed.

ally show themselves within this time) When nodes are palpable but movable, and not over 15 millimeters in largest diameter wait 6 weeks. If the nodes are fixed, or hard, and most probably carcinoma the operation for their removal is undertaken as a definite part of the initial treatment of the primary lesion, preferably at the same sitting. Occasionally the general condition of the patient will necessitate a division of treatment into two or more stages. These are usually desperate cases in which cure is hardly to be hoped for and as stated previously if metastases are present in any of the nodes above the hyoid

bone, subsequent operation for removal of the deeper lymph channels and lymph nodes must be performed on one or both sides. This operation extends from the clavicle to the mastoid process, and its degree of success is to be measured by the thoroughness of its performance.

In the case of V excision unless it is necessary to wait for confirmation of the diagnosis of cancer by microscopic examination of the excised tissue, the suprathyroid neck dissection is per-

formed at the same sitting. Should delay be occasioned by the lapse of time for the aforementioned confirmation of the diagnosis, the operation for removal of the lymph nodes is undertaken as soon as possible after the lip wound has healed.

Radiation, either from the radium bomb or from the X ray tube of proper voltage, has its strong advocates both as a prophylactic and curative agent in the treatment of metastases. There is little carefully checked clinical evidence advanced

to support this method. The fractional treatment by X ray (or radium) as advocated by Coutard has lately gained many sponsors. This method impresses me as more dangerous than surgery and requires much further trial before it can be generally accepted. Interstitial radiation on the other hand, has something to recommend it. When accurately employed, tumor tissue itself will absorb the brunt of the intensive radiation. Its success will depend upon the radiosensitivity of the tumor, the correct estimate of dosage and the accuracy of its application. The last can best be attained through operative exposure of the field to be irradiated. While I have yet to see a case of proved metastases cured by this method, I have observed such marked palliation without severe reaction to the patient that its use is to be recommended for inoperable cases.

I have not found the grading of either the primary tumor or of metastases to be of great value. We know that the more highly differentiated the tumor cells are, the less malignant and the less radiosensitive the tumor is apt to be. The converse is also true. Yet there are so many exceptions to this rule that it is not fair to the individual patient to base choice of therapy and prognosis

entirely upon the macroscopic appearance of the tumor.

SUMMARY

The treatment of cancer of the lower lip must be divided into two phases: the treatment of the primary lesion and the treatment of the adjoining lymphatic system.

In view of our present knowledge, the treatment of the primary lesion can be standardized. The important consideration is destruction of all cancer cells wherever they may be, and the structure of the lower lip permits this to be accomplished with equal certainty by either radiation or surgery. Practical considerations for the use of either method are described.

There is no standardized method for treatment of the lymph channels. The writer questions the value of radiation as a curative agent in the presence of metastases and finds no proof that its prophylactic use is warranted. Surgery when properly executed is definitely prophylactic and in many cases curative. Radiation has a place as a palliative procedure, its best effects being obtained by interstitial radiation, preferably combined with surgical exposure of the area to be radiated.

THE STANDARD TREATMENT OF MALIGNANT TUMORS OF THE BLADDER¹

WILLIAM E. LOWER, M.D., F.A.C.S., CLEVELAND, OHIO
Cleveland Clinic

THE frequency with which carcinoma of the bladder is encountered makes the consideration of what may be done for the unfortunate patients afflicted with this disease one of importance to every practicing physician and especially to every urologist. In the Cleveland Clinic we have found that malignant tumors of the bladder constitute 5 per cent of all cases of malignant disease in general, and almost half (44 per cent) of all cases of malignant disease in the genito-urinary tract.

Although there is no spectacular improvement or advancement in the treatment of this condition to discuss at the present time, perhaps an inventory of the situation may offer some encouragement and renewed hope for the future in combating vesical carcinoma. There have been no striking innovations recently, but by comparing the results obtained now with those of 20 years ago it is evident that there has been a slow but gradual improvement as the result of better diagnostic methods and of technical improvements in surgery and radiation therapy.

But the improvement in results already noted does not, in my opinion, mark the end of the road, for armed with these technical improvements and with the knowledge gained from the reviews of large series of cases, we may be able to reconsider and re-evaluate the criteria for operation with the result that more radical procedures will be undertaken in a greater proportion of cases with consequent improvement in end results.

A more optimistic outlook regarding bladder tumors is encouraged by the facts that the bladder is not a vital organ and can be widely resected or completely removed without jeopardizing the processes necessary to life, and also that bladder tumors tend to remain localized for longer periods of time than do cancers in many other parts of the body. The records show, of course that the proportion of local recurrences in the bladder is greater than elsewhere in the body but this tendency could probably be corrected by earlier diagnosis, more rigid vigilance regarding examinations subsequent to operation, and by more radical treatment at the outset.

The methods of treatment of carcinoma of the bladder have included fulguration, canterization, diathermy, radiation with radium and roentgen

rays, and various types of surgical removal, including excision, partial resection of the bladder and total cystectomy. All of these methods are still in use, and each has a definite field of usefulness, depending on the indications in the individual case determined by such factors as age, general condition, type of neoplasm, grade of malignancy, and the site of the lesion, as well as the technical skill and experience of the operator.

To accomplish a cure in any case of malignant tumor no matter where it is situated, demands that the growth be completely removed or entirely destroyed. Nothing less radical suffices. As long as the cancer remains localized, every effort should be made to remove it.

Unfortunately the complete removal of tumors in the urinary bladder offers difficulties which are sometimes insurmountable. Complete excision is seldom possible when the lesion occurs in the region of the base, the trigone, or the bladder neck. These areas are involved in 60 per cent of the cases in our experience. The growths which occur laterally even though they involve a ureter, or those at the vault of the bladder can be excised locally and should be so treated. A wide resection should be made for even though a large part of the urinary bladder is removed the remaining part expands to give ample vesical capacity, as has been demonstrated by the experimental work of Kretschmer. Patients who have had extremely wide resections of the bladder usually have very little discomfort.

If the ureter be involved, resection must include that part of the ureter. If the ureter is divided extraperitoneally, no special transplantation need be made for it will function, even though it is set back some distance. Provision should be made however, to prevent the formation of a stricture by eversion of the mucous membrane. If this does not seem feasible, the ureter may be transplanted in some higher point of the bladder. If transplantation is not possible, there can be no serious objection to ligating the ureter and putting the kidney out of commission, provided it is not infected and the opposite kidney is functioning normally.

Even in the case of recurrent malignancy in the bladder, a second resection may produce a brilliant result. In one patient on whom I operated,

there was a recurrence within a year. A second resection was done and the patient has been free of the growth for 25 years. This experience shows that a local recurrence is no contra indication to repeated attempts at excision of the growth.

In cases in which local excision or resection of a tumor of the bladder is impossible, total cystectomy may be done with the assurance of relief from the distressing symptoms attendant on an ulcerated, infected lesion in the bladder. Because of the relatively low incidence of distant metastases from bladder neoplasms, the indications for so radical a procedure as cystectomy are greatly enhanced.

Despite the indications for the procedure and the probability that the results would be as good or better than those from radical operations in other parts of the body, cystectomy has not been widely or generally used because of the technical difficulties involved. A transplantation of the ureters into the rectum is prerequisite to removal of the bladder. This operation requires a great deal of surgical skill and experience. Furthermore the excision of the urinary bladder is no undertaking for a novice in surgery.

Much of the improvement in the method of transplantation of the ureters and cystectomy we owe to the brilliant work of Coffey. His chief modification of the technique consisted of the application of the valve principle in the transplantation of the ureters into the rectum. In his final contribution to the literature, he reported a series of 11 cases in which the bladder had been completely removed. Seven of these patients were alive and well for periods of 4 months to 5 years. His comparatively low operative mortality rate of 27 per cent and the period of freedom from recurrence made the outlook in this type of case much more promising.

Recently Dr Charles C. Higgins of the Cleveland Clinic has made a further modification of the operation for uretero-intestinal anastomosis in which the ureters on both sides can be transplanted at the same operation, without interruption of the flow of urine into the bladder until the new channel between the ureter and bowel has been established. This method decreases the likelihood of pentoneal infection, which has been the greatest cause of death in this type of operation, and diminishes the morbidity after operation.

With these improvements in the operation, cystectomy is being performed with increasing frequency and I firmly believe that the more generally this operation is utilized, the less will be the proportion of recurrent and metastatic malignant lesions from bladder tumors.

When for any reason, surgical removal of the bladder does not seem feasible, fortunately another mode of attack, radiation, is available. The application of radium and roentgen rays for the wholly inoperable cases has given results that are most encouraging, in many instances. The indiscriminate use of small or large doses of radium by persons unfamiliar with its use and action has caused condemnation of a method of great merit. The best results in radium therapy can only be obtained by the close co-operation of physicist, pathologist and clinician.

The work of Barringer at the Memorial Hospital in New York demonstrates the value of skill and experience in the use of radium for the control of bladder neoplasms. In a series of 98 cases in which the clinical diagnosis was supported by biopsy 52.9 per cent of the patients with papillary carcinoma and 29.7 per cent of the patients with infiltrating carcinoma were alive and had no evidence of disease, according to cystoscopic examination, at the end of 3 years. Barringer feels that radium treatment is the method of choice and that the results to be expected from radiation are as good as those from surgery. The accessibility of the tumor must govern the choice of transurethral or transvaginal approach, and in all instances, an attempt should be made to apply a sufficiently large primary dose to destroy the tumor completely.

The same considerations are true of roentgen radiation. Since roentgen therapy has become a special field in medicine, the results of this type of treatment have been greatly improved. Deep roentgen therapy, however, in the treatment of bladder tumors is not so effective as the application of radium. In our own experience its use has been mainly palliative, but it may give many days and months of comparative comfort to an otherwise miserable creature. The occasional remarkable symptomatic relief and local regression of an extensive growth suggests that more widespread application in less formidable lesions might demonstrate a greater field of usefulness for this type of therapy. With the introduction of higher voltage machines in roentgen therapy it is quite possible that the results of this type of treatment might overshadow all others in malignant tumors of the bladder, especially if surgical procedures would be extremely difficult, or impossible.

Although surgical removal and radiation are respectively the most important methods of treatment in cases of carcinoma of the bladder, fulguration and cautery may still be useful in certain cases, especially in very small lesions, extremely early growths or those of a very low grade of

malignancy. The important point, of course is to destroy the lesion entirely, and if that can be done by some less radical procedure, the results obtained may be excellent. Several of our patients were thus treated very satisfactorily.

Surgical diathermy has been advocated by a number of urologists, and seems to produce good results in certain cases in which operation can not be performed (7, 10). It probably has some place in the armamentarium of the urologist in certain types of cases.

SUMMARY AND CONCLUSIONS

As has already been mentioned most authorities agree that the incidence of distant metastasis from tumors of the bladder is considerably lower than from other neoplasms. The Carcinoma Registry of the American Urological Association (3) has estimated that metastasis occurs in only 10 per cent of the cases. Other estimates have placed this figure at 20 per cent or even higher. Some writers have contended that the incidence of metastasis depends on the degree of malignancy of the lesion (7). In view of these statements the report of Smith and Mintz is most interesting, for they state that in a study based on 34 post mortem examinations at the Massachusetts General Hospital, metastasis was revealed in 16 instances, or almost 50 per cent. Their demonstration that the tendency to metastasize is not related to the grade of malignancy is significant and indicates clearly the necessity for regarding every case of tumor in the bladder as either potentially or actually cancerous.

The Carcinoma Registry found in an analysis of 902 epithelial tumors of the bladder that there had been a recurrence in 46 per cent of the cases (3). They also have pointed out that the incidence of metastasis is higher in cases in which the tumor is most easily resectable, that is, high in the vault of the bladder. Most of these tumors were found to metastasize to the liver, because of the direct pathway through the lymphatics of the hypogastric vessels. These facts emphasize the necessity for increased vigilance in following the course of each patient after operation and also show that more radical operations probably are indicated and might produce very much more satisfactory results.

In conclusion, although I have no revolutionary procedure to advocate in the treatment of carcinoma of the urinary bladder I feel that we should all be heartened by the evidences of the gradual development which has already been accomplished. Merely to contrast the results in a few relatively recent series of cases with those

reported by Watson in 1913 and by Gardner in 1915 shows that there has been a perceptible increase in the number of 3 and 5 year cures. They reported the number of 3 year cures following resection as 14 and 22.5 per cent respectively. In our own series 28.5 per cent of the patients subjected to operation and radiation have survived for 5 years or more. A recent series of cases reviewed at the Mayo Clinic (4) reported that 28 per cent of patients with carcinoma of the bladder survived 5 years or more. The Carcinoma Registry (3) in its recent report of 902 cases numbered the 5 year survivals at 33 per cent. At the time of Watson's and Gardner's reports the treatment was limited largely to excision and partial resection, whereas today we can resort to cystectomy, with increasing confidence, and have recourse also to radiation therapy—an important adjuvant if not the sole hope of patients with advanced disease.

Today's results are still far from what we might wish and also, I believe, from what we may actually accomplish. With certain physiological and pathological factors more favorable than in tumors elsewhere in the body, we should face the problem of treatment of malignant disease of the bladder with new confidence that there will be a steady improvement in the final results in this type of case.

SYMPOSIUM TREATMENT OF FRACTURES

ONE THOUSAND CONSECUTIVE FRACTURES OF BOTH BONES OF THE LEG¹

WILLIAM SINGER, M.D. F.A.C.S. AND J. SIMS NORMAN, M.D. F.A.C.S. PUEBLO, COLORADO

TRAUMATIC surgery has come into its own. The wonder of it all is that it required the tragedy of a World War to focus our attention on the importance of this branch of medicine. As a specialty it lagged because the general practitioner treated trauma as a side issue—a bore and a hazard. He gave little thought to its importance and little study to its anatomy, pathology and end-results. The War forced the issue. Expansion of industry, development of automobile and airplane have broadened the field and sharpened the interest of our profession. Traumatic surgery now challenges the attention of our manufacturing plants great and small. Industrial Commission awards which have been based on both anatomical and functional perfection in the results of fracture treatment have spurred this newer surgery forward. It is for this reason that the evolution in fracture treatment has had to be rapid. There has been much room for progress.

In a review of 1,000 consecutive fractures of the tibia and fibula covering a period of approximately 17 years, one's mind passes in review the numerous examples of cumbersome and expensive beautiful and worthless reduction apparatus which clutter our basements. Gradually simpler and better tools made their appearance. To be successful these appliances must be the result of sound physiological, reconstructive and rehabilitative reasoning.

When invited to present a paper at this meeting we felt that some of the rather obvious things in this group of cases would be interesting—possibly instructive.

We see many fractures, because the Corwin Hospital is the concentration point for diseases and injuries of the Colorado Fuel and Iron Company employees and their dependents. Our company operates a large steel plant in Pueblo. Iron mines in Wyoming, coal mines and lime quarries throughout Colorado. All fractures of any consequence are splinted by the local physician and sent to us.

In considering fractures of both bones of the leg as an entity we note—

- 1 That this is a very frequent industrial injury.
- 2 That no other major fracture is compounded so frequently. This is due to the close proximity of the bones to the skin and to the terrific force required to fracture both bones.
- 3 That the site of fractures from direct violence is most frequently at the weakest point—the point between the middle and lower third of the leg. Fractures due to indirect violence are often of the spiral type.
- 4 That no other fractures are so prone to non-union. It is our opinion that muscle attachments with their rich blood supply have much to do with bone union. There is an absence of such attachments in the region of the middle and lower third of the leg. Besides, when fractured, the ends of the fragments usually are separated completely from surrounding tissue. If our original assumption be correct, it readily explains non-union in this situation.
- 5 That any trauma of sufficient force to fracture both bones usually greatly damages the soft parts. Sometimes our efforts are concentrated, therefore on the co-existing surrounding injuries rather than upon the bones themselves.

TREATMENT

In the time allotted we must be dogmatic and not argumentative. Whatever we have found of greatest value is here described.

- 1 Every severe fracture case is potentially or actually in shock. No reduction should be attempted until this complication is alleviated.
- 2 If not contra-indicated, the fracture should be reduced immediately and plaster cast applied. In the simplest fractures with little displacement we use local anesthesia. Even in these cases, however, we must have the active co-operation of the phlegmatic patient. Spinal anesthesia is ideal if we bear in mind its contra-indications. But our main reliance has been placed on nitrous oxide and oxygen with ether. Generally speak

¹Presented in the symposium on the Treatment of Fractures, before the Clinical Congress of the American College of Surgeons, Boston, October 25, 1934.

ing ether gives the greatest relaxation with the least hazard.

When the fragments are so fixed that we feel it practicable, a Boehler walking iron is incorporated in the cast. One of us (J.S.N.) became enthusiastic about this method after visiting the Boehler clinic. Further study, however, makes us believe that it is not safe to use it as routinely as Dr Boehler does.

3 Theoretically, every compound fracture should be made a closed fracture through immediate surgery. Unfortunately, the trauma may seriously damage blood vessels and nerves devitalize the skin, muscles, tendons, fat, and fascia. Our first investigation, therefore, should be concerned with the viability of the limb as a whole. Then our attention should be directed to the sterilization of the surrounding skin—shaving, scrubbing gently with soap and water, bathing in ether, and finally applying tincture of iodine. All of this should be done with meticulous care so as not to contaminate the open wound with foreign substance. Next the wound is washed thoroughly with large quantities of saline solution. Tincture of iodine is then poured into the wound. While we do not feel that iodine will sterilize the multitude of crevices open to infection, we believe it should always be used. It probably helps. Apparently it does no harm.

Mechanical sterilization, however, is of the greatest importance. The skin edges are cut away. All devitalized tissues, whatever their character, must be removed by sharp dissection. Constantly we watch lest the scalp graft potential infection into clean tissue. Of late we have performed débridement with the "radio knife"—much to our satisfaction.

Sometimes, in severe wounds it may be almost impossible to trace all small crevices. Here we have found it of advantage to counterstain with methylene blue. The tracts may then be followed as is done so frequently in ramifying fistulae elsewhere in the body.

If the bones have been ground into dirt the ends are trimmed. Pieces of entirely detached bone are removed. Adherent fragments are placed in a position most advantageous for healing. Thus do we carry out débridement, with no finger contact technique.

The next step is to suture the severed soft parts, nerves, tendons, and muscles. Absolute hemostasis must be the rule. The skin is sutured without tension. If it cannot be approximated relaxation is accomplished by longitudinal incisions some distance from the wound. The skin is never undermined. Drainage is never inserted.

Extension is always applied by the skeletal method. We use almost routinely the Steinmann pin, rarely the long calipers or Kirschner wire. Traction is followed by applying a plaster cast.

4 Markedly comminuted fractures or those which we are not able to reduce early are treated by skeletal traction. For these we prefer a small Steinmann pin through the os calcis and a Hawley suspension splint. It must be emphasized repeatedly that overtraction separates fragments and produces non-union.

5 While it is our policy to avoid open reduction when possible, we open spiral fractures of the tibia with the fibula broken high. We believe time, suffering and disability are thereby reduced to a minimum.

6 We prefer to use autogenous substance in our open reductions and almost never use non-absorbable material. Metal plates have been used with some excellent results, but experience urged us to abandon them.

7 During the recent past we have used an automatic device designed by Dr Roger Anderson of Seattle. This apparatus we believe is a most excellent tool for proper fixation of fractures of the leg. It is based upon simple anatomical principles with ample traction and facilitates manipulation. It does not interfere with the application of plaster and leaves the bones transfixed. Since it can be easily autoclaved, we have found this apparatus particularly helpful in our open work. Even with this apparatus let us emphasize once more the importance of preventing overtraction.

Sometimes we have accused ourselves of ultra-conservatism in our attempts to save shattered limbs. How much simpler and easier to amputate! After months of constant treatment we may have a patient with a 50 per cent or even 25 per cent functioning limb. However, we have the satisfaction of knowing that psychologically this patient is far more of a man than were he to possess the best artificial limb that money can buy.

Of the 1176 fractures treated at Corwin Hospital since 1917, 1,000 were fractures of both bones of the leg.

In reviewing these cases we find a comparatively high proportion compounded, namely, 231. These were treated along the lines already set forth. In spite of these efforts 21 of them became infected, 31 failed to unite and subsequent bone graft was indicated. It was also necessary to reduce 54 fractures of other types by open method.

Amputation was necessary in 11 cases. These should probably not be considered here because of the primary seriousness of their injury. In the 1,000 cases there were 19 deaths. These were all

SYMPOSIUM TREATMENT OF FRACTURES

ONE THOUSAND CONSECUTIVE FRACTURES OF BOTH BONES OF THE LEG¹

WILLIAM SINGER, M.D. F.A.C.S. AND J. SIMS NORMAN, M.D. F.A.C.S. PUEBLO, COLORADO

TRAUMATIC surgery has come into its own. The wonder of it all is that it required the tragedy of a World War to focus our attention on the importance of this branch of medicine. As a specialty it lagged because the general practitioner treated trauma as a side issue—a bore and a hazard. He gave little thought to its importance and little study to its anatomy, pathology, and end-results. The War forced the issue. Expansion of industry, development of automobile and airplane have broadened the field and sharpened the interest of our profession. Traumatic surgery now challenges the attention of our manufacturing plants, great and small. Industrial Commission awards which have been based on both anatomical and functional perfection in the results of fracture treatment have spurred this newer surgery forward. It is for this reason that the evolution in fracture treatment has had to be rapid. There has been much room for progress.

In a review of 1,000 consecutive fractures of the tibia and fibula, covering a period of approximately 1 year, one's mind passes in review the numerous examples of cumbersome and expensive beautiful and worthless reduction apparatus which clutter our basements. Gradually simpler and better tools made their appearance. To be successful these appliances must be the result of sound physiological, reconstructive and rehabilitative reasoning.

When invited to present a paper at this meeting we felt that some of the rather obvious things in this group of cases would be interesting—possibly instructive.

We see many fractures, because the Corwin Hospital is the concentration point for diseases and injuries of the Colorado Fuel and Iron Company employees and their dependents. Our company operates a large steel plant in Pueblo, iron mines in Wyoming, coal mines and lime quarries throughout Colorado. All fractures of any consequence are splinted by the local physician and sent to us.

In considering fractures of both bones of the leg as an entity we note—

1. That this is a very frequent industrial injury.
2. That no other major fracture is compounded so frequently. This is due to the close proximity of the bones to the skin and to the terrific force required to fracture both bones.
3. That the site of fractures from direct violence is most frequently at the weakest point—the point between the middle and lower third of the leg. Fractures due to indirect violence are often of the spiral type.
4. That no other fractures are so prone to non-union. It is our opinion that muscle attachments with their rich blood supply have much to do with bone union. There is an absence of such attachments in the region of the middle and lower third of the leg. Besides, when fractured, the ends of the fragments usually are separated completely from surrounding tissue. If our original assumption be correct, it readily explains non-union in this situation.
5. That any trauma of sufficient force to fracture both bones usually greatly damages the soft parts. Sometimes our efforts are concentrated, therefore on the co-existing surrounding injuries rather than upon the bones themselves.

TREATMENT

In the time allotted we must be dogmatic and not argumentative. Whatever we have found of greatest value is here described.

1. Every severe fracture case is potentially or actually in shock. No reduction should be attempted until this complication is alleviated.

2. If not contra-indicated the fracture should be reduced immediately and plaster cast applied. In the simplest fractures with little displacement we use local anesthesia. Even in these cases, however, we must have the active co-operation of the phlegmatic patient. Spinal anesthesia is ideal if we bear in mind its contra-indications. But our main reliance has been placed on nitrous oxide and oxygen with ether. Generally speak

¹Presented in the symposium on the Treatment of Fractures before the Clinical Congress of the American College of Surgeons, Boston, October 24, 1934.

results are actually impossible. In many other cases, however, poor results may be due to the following factors

1. Insufficient anatomical reduction because of inadequate equipment.

2. Insufficient care of the wound followed by infection in open fractures.

3. Numerous vain attempts at conservative treatment in fractures which are of such a nature that perfect anatomical and functional results can be obtained only by operative intervention.

4. Lack of skill and experience in the technique of operative treatment of fractures.

5. Tardy hospitalization of poorly set fractures, with consolidation in incorrect position and permanent injury due to subsequent incorrect position of the adjacent joints.

This latter fact receives too little attention, not only from the general practitioner but also from the surgeon in some cases. The fracture must not be looked upon as an isolated injury but the bone, the muscles, and the adjacent joints must be considered as a functional and physiological unit.

6. In injured patients psychological factors must also be held partially responsible for unsatisfactory results. There are cases in which the anatomical position is perfect but the patient develops compensation neurosis and the result is functional impairment of the condition.

We will now describe briefly, on the basis of the extensive fracture material of the surgical clinic of the University of Freiburg (Germany) the methods by which we achieved the best results in operative treatment of fractures of the long tubular bones. Purposely very few figures will be given because statistics give little information concerning the ways and means by which good results are obtained in the individual case. Table II covers the fractures treated during a period of 7 years.

TABLE II

	Cases	Per cent
Total number of fractures treated	12,000	100.00
Treated in clinic (hospitalized)	1,245	10.37
Operatively treated	306	2.54
Bone plating	75	0.63

It will be noted, therefore, that of 12,000 cases 1,245, or 10.37 per cent, were hospitalized. Of these 1,245 cases 306, or 24.58 per cent, i.e., approximately one fourth, were treated by operation. In this latter group there were 75 cases, or 24.51 per cent in which plastic repair was done by means of bone plates.

Let us also consider a few data concerning the frequency of fractures of the long tubular bones and their skeletal distribution. Table III shows

the distribution and frequency in a collection of 9,160 fractures treated in the Freiburg clinic in the course of 6 years.

TABLE III

	Cases	Per cent
Total number of fractures	9,160	100.00
Upper arm	693	7.57
Forearm	1,850	20.20
Thigh	482	5.26
Lower leg	2,100	22.93

These figures show clearly the frequency with which fractures force the physician to be particularly exact in the matter of indications. The type of anaesthesia, the time of operation, the operative technique, and the preliminary and after treatment are all important factors in the individual indication. A brief review of each of these points is given in the following sections.

NARCOSIS OR ANAESTHESIA IN OPERATIVE TREATMENT OF FRACTURES

If the type and location of the fracture and the procedure to be used in treatment are such that the physician can manage without general anaesthesia, local anaesthesia should be used. In extensive interventions—bone plating for instance—in psychically unstable patients, general anaesthesia should always be given. In fractures of the lower leg in which operative reduction is easily accomplished by approximating the fragments with a hook, local injection is sufficient. When wire is to be applied to fractures of the lower leg and of the thigh we frequently use lumbar anaesthesia. In cases in which the fractured bones lie close to the surface we occasionally inject novocaine at the point of fracture, as recommended by Boehler. In the upper extremity one can some times use Kulenkampff's plexus anaesthesia. We have frequently used it with good results but in a few instances the results were unsatisfactory. Koenig urgently recommends cross-sectional anaesthesia, in which radial injection down to the bone is done at 4 or 5 places about a handbreadth above the region of operation, so that the novocaine solution acts upon the periosteum, the muscles, and the skin. Infiltration must be done also along the line of incision. In operations which can be completed within a short time I have recently begun using intravenous Evipan anaesthesia, especially in fractures of the lower leg. In some cases local anaesthesia is combined with it. This combined method has shown itself to be excellent.

¹Details about this combination of local and intravenous anaesthesia in fractures are being published in *Anaesthesia and Analgesia* 1933 March.

TIME OF OPERATION

Another important factor in good operative treatment of fractures is the time at which operation is performed. With the aid of examples let us now study a few types of fracture, in some of which immediate operation is indicated while in others, later operation is advisable. Of course we do not pretend to cover all possible types of fracture.

Immediate operative intervention is indicated in only a few cases

1 In complicated severely dislocated fractures of the lower leg. At the time of primary excision and wound treatment the misplaced ends of transverse fractures are approximated with a hook after conservative reduction has been found impossible.

2 In simple or compound, badly dislocated transverse and spiral fractures of the lower leg in which correct position cannot be achieved by immediate closed reduction.

3 In fractures of the forearm in which the displacement of the 2 bones frequently cannot be corrected by closed reduction. Here it is often a matter of transverse fracture of the shaft, in which reduction may readily be accomplished by simple approximation.

4 In fractures whose dislocated fragments induce injury to nerves or vessels. In such cases operation sometimes shows the nerve riding upon the pointed fragment.

5 In joint fractures.

6 In cases with large fracture hematoma which may induce severe compression of vessels and nerves (ischæmia). This is known to occur in fractures of the elbow. Immediate relief should be given by splitting of the fascia, drainage of the hematoma, correction (with wire suture if necessary) etc.

In other words, the above types of fracture are those in which operative treatment should be given immediately. They are fractures lying superficially in which either conservative reduction is not possible or the associated skin injury demands operative treatment even though other soft parts are not particularly injured and finally this group includes fractures in which the associated injuries are such as not to permit delay in treatment of the fracture until the most convenient time.

In all other cases we usually look upon the second week as the optimal time for operative treatment of the fracture. Koenig, Lambotte, Rehn and others are of the same opinion and operate about the beginning or the middle of the second week. Lexer designates the fourth and fifth as well as the second week as favorable. He

bases his opinion upon his investigation which showed that fracture hyperæmia is most highly developed during this period. Doubtless the choice of time for operation is dependent upon the physiopathological processes which occur in connection with the fracture trauma. Along with the degenerative changes in bone, lacerated periosteum, and damaged muscles, which occur immediately after injury, there soon appear regenerative processes of which the surgeon makes use. In this connection the physiological response of the muscles plays a part which often is overlooked. The physiological balance of the muscle tone between flexors and extensors is a necessary factor in the healing of fractures. This is achieved only by firm fixation of the broken bone in good position. Immediately after fracture the muscles involved are in a state of subnormal excitability, which persists for about 8 days and is designated as a sort of "muscular stupor" (Rehn). Then from the eighth to about the thirtieth day after fracture there is a state of "intermittent tetanic hyperexcitability of the muscle." The correlation between the fracture and the muscle is of outstanding physiological importance. This muscular activity is necessary in all of those places where the callus must be furnished by the periosteum alone i.e. in the diaphysis. It is encouraged by absolute rest of the injured member and extension according to physiological condition. Insufficient rest and too great a degree of extension prevent physiological activity of the muscles (electric action currents) and so defer callus formation. This retards healing of the fracture or prevents it entirely.

The large number of pseudarthroses or non-united fractures observed during the last few years is due partly to the fact that the fractures were not fixed firmly enough and were not left in the plaster long enough, or to the use of too great extension.

INDICATIONS

It is erroneous to suppose that operative treatment of fracture is permissible only after long use of conservative measures has proved useless. By postponement of necessary operative correction conditions may be created which impair the operative result or even make a perfect result impossible. We must see to it that operative treatment is given at a timely period in all cases. Operation should be done before the regenerative capacity of the fractured bone is exhausted and before retraction, contracture, atrophy of the muscles, and contractions of the capsule and ligaments of the adjacent joints have induced permanent injury.

Fig. 1. Spiral fracture of the lower leg with severe dislocation and interposition of musculature. When conservative measures failed operative reduction and suture with metal bands was done according to the method of Parham Putt.

Fortunately these views are gaining more and more ground, although even today there is still not complete agreement among the various authors. The statistics given above show that in our clinic 2.54 per cent of all fractures are treated by operative procedure. Magnus performed operation in 3 per cent of his cases, and the Goettingen clinic (Stich) in 2.8 per cent of all fracture cases. These figures come from 3 clinics with extensive bone material. One is probably justified, therefore in saying that approximately 3 per cent of all fractures must receive operative treatment. But if we consider the number of hospitalized cases we have a much higher percentage of operations i.e., 24.58 per cent, or practically one-fourth of the fractures.

Generally speaking operative treatment of fractures is indicated (1) when perfect anatomical reduction cannot be accomplished (2) when closed fixation of the fragments is impossible, and (3) when consolidation fails to occur.

We will now discuss these indications as they apply to individual cases and on the basis of our experience describe the effective operative treatment.

OPERATION IS INDICATED

1. When conservative measures have failed in spite of the use of all technical devices such as fracture table, countertraction wire extension etc. Numerous manipulations repeated at short intervals, contusions, and traction on the soft parts injured by the fracture enlarge the hematoma and disturb the physiological repair of the

Fig. 3. An ideal anatomical result was obtained by wiring.

tissues. This increases the danger of slight or late callus formation and of subsequent pseudarthroses.

2. In fractures in which muscle interposed in the fracture makes conservative reduction impossible from the beginning.

of the tibia cannot be reduced and placed one upon the other because of interference from the fibula, a piece of the latter must be resected.

6 In cases of transverse fractures of the upper arm and thigh, in cases in which perfect position cannot be achieved by extension with Kirschner's wire or leucoplast, etc. In this group should be placed also the oblique fractures and spiral fractures of the femur, whose reduction is rendered difficult by the thick masses of muscle of the thigh. As a general thing one attempts to obtain

reduction with traction more frequently in the upper arm than in the thigh because the danger of operative injury is doubtless greater (injuries to the radial and the axillary nerves, atrophy of the deltoid muscle, etc.)

7 In fractures of the forearm, the relative frequency of inadequate consolidation in these fractures is well known. In this group pseudarthroses are most readily avoided by exact operative reduction if conservative measures do not succeed.

Fig. 22

Fig. 25: Operative exposure, fixation of the fragments with laterally placed metal splint firmly fastened with wires. Distinct callus formation. The fracture is firm at end of 6 weeks.

8. In cases of delayed callus formation due to laceration of the periosteum or inadequate vascular supply as a result of laceration of the nutritive artery. In these cases operative freshening of the fractured ends may produce the desired results.

9. In pseudarthroses (non-united fractures). Here operative intervention is the only therapy which can produce results.

TECHNIQUE

As a matter of principle we operate upon fractures without the use of a tourniquet. In order to avoid secondary hyperæmia and hematomata we prefer exact hæmostasis in the tissues. Rapid incision through skin, fascia, muscle and periosteum is the most sparing to the tissue. Large incisions are necessary for the most careful exposure of the bone. In the thigh we prefer to place the incision on the lateral side at the anterior border of the musculus

tensor fascia lata. In the lower leg we use a longitudinal incision a fingerbreadth lateral to the anterior border of the tibia. In the upper arm we use either Langenbeck's resection incision or the Dollinger incision at the medial border of the deltoid muscle. Longitudinal incisions through the deltoid muscle may lead to atrophy and motor disturbances and should therefore be avoided. The soft parts are not held aside with sharp hooks but with blunt retractors. Care should be taken not to separate the periosteum from the muscle because this might result in nutritional disturbance to the periosteum and subsequent weakness of the callus.

In the following we shall give a few cases which we operated upon in our clinic. Technique, indications, and results are shown more distinctly by a few examples than by statistical tables.

Among the fractures of the lower leg we have (Fig. 1) a spiral fracture of the tibia with severe dislocation together with unpalement and interposition of the muscles. Conservative measures were unsuccessful. Therefore two small metal bands were applied according to Parham-Putti technique. The condition before and after operation is shown in the picture.

In many similar cases we have obtained fixation of the fragments by simply winding two wires about them.

In fracture of the thigh we use different methods according to the individual case. In spiral and oblique fractures retention and fixation of the fragments can be obtained by wire suture applied after reduction to anatomical position (Figs. 2 and 3). If setting fails because of slipping of the fragments we must consider using splints of either autogenous or foreign material. As a general thing we do not approve of drilling through the bone and applying numerous screws, as some surgeons recommend. According to our opinion

Fig. 26

Fig. 26: 9 year old boy: transverse subcapital fracture of the humerus.

Fig. 27: T: metal splints are fastened with 3 wires over the site of the fracture. Because of the shortness of the proximal fragment simple wiring of the fracture would not

Fig. 27

Fig. 28

be held, consequently three canals were drilled into the bone and the wires were passed through them.

Figs. 27 and 28 show the position of the metal splint and the position of the fracture from the front and from the side.

Fig 29

Fig 29. Patient was a girl 13 years old, who suffered a supracondylar fracture of the humerus with severe displacement and interposition of the soft parts. Large hematoma. Conservative measures unsuccessful in effecting a satisfactory union.

Fig 31

drilling through the cortex in a number of places and on both sides of the bones injures even the normal bone, and this injury would be all the more marked in a bone which has suffered a recent fracture and is in the process of destruction and regeneration. Therefore, in lateral splinting, we apply a new narrow perforated splint of stainless steel and fix it in position with 2 or 3 wires much the same as in simple wrapping with wire. You see a result of this treatment in Figure 6. This picture is of interest also because it shows a generalized osteitis fibrosa (Fig 4). You will see a number of foci in the right and left thighs. This same case showed fibrous bone foci in both upper extremities also. This 14 year old boy suffered a spontaneous fracture which you see in Figure 5.

In this case as shown in Figure 6, operative reduction of the fragments was done, fixation was accomplished by metal splint with wire sutures. The case is worthy of note because it shows that even bone with pathological changes healed with out reaction over the stainless steel splint which we used. We examined the boy half a year later. The fracture was firm and the foreign body was healed over with such complete absence of reaction that we decided not to remove it.

The metal splint technique just mentioned is especially successful in youthful patients with transverse shaft fractures which cannot be treated successfully with conservative extension therapy. In vigorous individuals however, even this splinting may be too weak for the strong musculature.

Fig. 37 Lateral picture. perfect anatomical position, large callus at the medial side of the shaft.

of the thigh. In such cases we prefer the stronger splinting by free autoplasmic transplantation of bone taken from the tibia. This method was developed by Lever. In our series of 12,000 fractures we have used it 75 times in the course of 7 years. It is important that the bone splint be of sufficient length and thickness and be fixed with absolute firmness to the fragments with wire. Figures 7, 8 and 9 show clearly the result of such operative repair in the thigh. The method can be used with excellent success in severely dislocated transverse fractures and especially in non-united fractures (pseudarthroses). Even though, in beginning pseudarthroses, freshening and drilling of the fragments (a method originally devised by Dieffenbach and recently revived by Beck) produces the desired effect, there are still numerous cases which will respond only to the bone splinting method just described. Absolute immobilization for 10 to 12 weeks is indispensable in these cases. Of course the foreign body must be allowed to remain longer in these cases because it fixes the bone splint. In most cases the wires become firmly embedded in the splint and in the parent tissue and heal over so that their removal is not necessary.

A further case showing the indication for wire suture in comminuted fracture is illustrated in Figures 10 and 11. A man, aged 65 suffered severe trauma resulting in spiral fracture with separation of a fragment of bone. The fracture

Fig. 38 Shows the condition of the bone after 8 months. Very good anatomical position of the femur. the fracture is firm, the plate of bone and the wires have healed over without reaction.

was sutured with wire and showed ideal position of the fragments 7 weeks later.

This is the case of a girl aged 21 who suffered a severe comminuted fracture of the upper arm (Fig. 12). There was a fracture in the middle of the shaft and another splintering comminuted fracture at the surgical neck of the humerus. Here neither extension nor other reduction maneuvers could produce good results. We therefore used an autoplasmic bone splint for the fracture of the shaft and impaction for the subcapital fracture of the humerus. The two control pictures (Figs. 13 and 14) show the anatomically perfect result after 6 years. The fractures are firm, the bone splint and the wire healed over without reaction and clinically there are no essential functional limitations.

The next case (Figs. 15 and 16) shows a longitudinal fracture of the lower end of the humerus involving the elbow joint. If such a joint fracture is not reduced to perfect anatomical position, it induces secondary arthritis deformans. For this reason operative reduction of the fracture was done. By means of a dorsal incision ideal position of the fracture and of the joint was obtained with only one wire suture. (Fig. 17—after operation in plaster.)

In the next case (Fig. 18) we have a severely comminuted fracture of the elbow joint. If such a case is treated by conservative measures there will be stiffness of the joint. Here the shattered

Fig 40 Flexure of the knee joint after operation.

Fig 41 Efficient functioning of the joints of the fractured lower extremity

elbow joint and the upper end of the forearm were opened by dorsal incision and the fragments reduced to the best possible anatomical position with the aid of 2 metal splints and wire sutures (Fig 19 immediately after operation, Fig 20, 4 weeks after operation, Fig 21 10 weeks after operation). The pictures show that the fragments became joined and are fixed in perfect anatomical position. The buried metal splints were later removed. The motility of the joint amounted to 60 per cent of the normal.

Figure 22 shows a fracture of the radius in which the entire epiphysis was split off and dislocated dorsward. If such a case is treated conservatively the wrist becomes stiff. Through a small incision one can bring the epiphysis back to the shaft of the radius and fix it there with a single wire suture. The perfect anatomical result is shown in Figure 23. Clinically the wrist showed normal function.

Bone fractures in children usually should receive conservative treatment, but there are cases in which even children's fractures justify or even demand operative therapy. During the last few years open reduction has been necessitated in many instances by the increasingly frequent serious traffic accidents which cause severe types of fracture such as formerly were hardly known. Mastery of the operative technique of fracture treatment makes it easier for the surgeon to make up his mind to operate even in youthful patients when conservative measures fail.

Figure 24 illustrates a transverse subcapital fracture of the humerus in a 9 year old boy. Here even the type of fracture shows that neither conservative treatment nor simple wrapping with wire could have achieved firm fixation of the fracture. For this reason (Fig 25) a metal splint was sutured upon the fracture and fastened with 2 wires. Anatomical position and function of the humerus were perfect.

In a similar case of subcapital fracture of the humerus in a 10 year old boy, a variation of this technique was used. Three canals were drilled through the fragments and 2 metal splints were wired in place, one to either side of the humerus (Figs. 27 and 28). Fixation of the metal splints by means of drilled canals is necessary only in cases like this because if the wire were merely passed around the bone without a drilled canal the wire would slip off because of the shortness of the proximal fragment.

Supracondylar fractures of the elbow cannot always be reduced perfectly by conservative measures. If closed reduction fails, as in the case of this 13 year old girl (Fig 29) the fracture must be exposed and operative correction must be performed. In this case there was separation of the entire joint surface of the lower end of the humerus. It was attached to the shaft of the humerus by means of a metal splint and 3 wire sutures, as you see in Figure 30. After 10 weeks the splint and wire suture were removed. Figure 31 shows a perfect anatomical reconstruction of the elbow joint.

and Figures 32, 33, and 34 show the ideal functional result (complete extension, complete pronation and supination, and maximal flexion).

Fractures of the femur in children, especially transverse fractures, may likewise fail to respond to conservative treatment as is so often the case in adults. In a series of 60 fractures of the femur in children which I reported in a recent article, there were 8 cases in which we were forced to use bone plating in spite of the youth of the patients; all were transverse fractures of the femur. Figure 35 shows the transverse fracture in an 8 year old boy. Figures 36 and 37 show the condition 6 weeks after operation with bone plate wired over the fracture. You see the end-result after 8 months in the next picture (Fig. 38). Bone plate and wires have healed over without reaction and the anatomical position may be designated as ideal. The normal functions of the thigh and of the joints are shown in the next pictures (Figs. 39, 40, and 41).

Of interest in all of these cases is the formation and resorption of the callus. As a general thing we may say that the poorer the position of the fracture the more callus is necessary for rebuilding the normal structure of the bone and the better the position the less callus is needed.

As you will gather from the facts just given, we may say that the results of the operative treatment of fracture are good. On the basis of my observations in 12,000 fractures in the course of the last 7 years and with the aid of various examples, I have given the indications for and the technique of operative treatment.

It is not our intention to minimize the importance of conservative treatment of fractures in emphasizing operative therapy. It produces equally good results within its realm of indications. But the difficulty lies in the exact definition of the limits of operative and non-operative methods. Only experience with a large number of cases can teach us when it is permissible to use the conservative method and when the operative method must be used. Neither of them is in itself the method of choice.

In art there are various styles; in surgery there are various methods. Both have an analogous purpose—the creation of a work of art. Neither style nor method in itself is good or bad. The

intuition and technique of the artist will create a masterpiece with any style, whether classical, baroque, or modern. With a correct grasp of the method which is indicated in the individual case and complete mastery of its technique the surgeon will be able to create a masterpiece with conservative as well as with operative measures.

FRACTURE OF THE (NAVICULAR) CARPAL SCAPHOID¹

JOSEPH H. BURNETT M.D., F.A.C.S. BOSTON, MASSACHUSETTS

FRACTURES of the carpal scaphoids while apt to be very crippling to the individual unfortunate enough to have sustained one, have up to comparatively recent times received very little attention from general practitioners, X ray men and surgeons alike. Many of these wrists are treated either by the patient or by the doctor without an X ray, erroneously, as sprains, until too late to be given the proper treatment. The writer believes that these cases are worthy of more consideration and brings to the attention of those interested in this work a method of treatment that is apparently working out well, with a view to stimulating others to use it.

SYMPTOMS

This is one condition that "runs true to form inasmuch as most of the cases have almost identical complaints. Chief and foremost is pain at the site of fracture disability and pain on pushing limitation of dorsal flexion, local tenderness, and a marked weakness of the wrist as a whole. Occasionally there is a poor grip but this is usually the exception.

PROGNOSIS

From a clinical standpoint the unrecognized or tardily recognized fracture offers a progressively poorer prognosis in direct ratio to the length of time since fracture. Many in fact most of these cases are seen in the younger age groups and are most crippling, far more so than the average Colles fracture poorly treated or untreated. A group of 37 cases reported by the writer in 1929 from the Out Patient Department at the Boston City Hospital showed over 60 per cent to be 30 years of age or less. If bone absorption cavity formation and local irritation with new bone formation have started, it may be possible to check this by operating upon the scaphoid i.e. either removing part or all of it or by the grafting operation. It has been clearly shown by experience that the removal of the scaphoid has not produced a satisfactory result in all cases hence the resort to the graft. The cases with old fractures however offer a poor prognosis. These old cases are often crippling many of them giving a practically stiff wrist with chronic weakness and pain. In all fairness I think it can be said that in some of the recent cases good results occur with or without treatment and that in some of them progress is poor regardless of the treatment. In many recent

cases a very fine fissure fracture is often overlooked by physicians unfamiliar with them, and if not treated a heavy line of absorption is evident within a very few months. The following case shows this condition plainly

CASE 1 T. C. aged 34 years, laborer. Injured his wrist May 20, 1932 lifting a roll of paper. Roentgen films showed a fissure fracture and the patient was treated with anterior and posterior splints for 4 to 5 weeks with baling and massage. He was out of work practically 4 months. In July 1933 he was re-examined because of the condition of his wrist, namely pain, weakness, inability to push or to flex wrist dorsally. The film taken at that time showed marked absorption almost to the extent of cavity formation. Operation was advised, but the patient was unable to make up his mind.

Recent fractures seen early and properly treated do rather well as a rule. These cases, properly treated showing a poor result at the end of 3 to 4 months or more, should be operated upon at that time inasmuch as they will get progressively worse. In complicated cases with separation of the fragments early removal should give a favorable result.

TREATMENT

Recent cases in good position are best treated by immobilization and rest, with the hope that bony union will occur. There is considerable difference of opinion as to just how the hand should

Fig 5 Same patient, September 2 1933

be held at this time, many using the cock up position and many others using the reverse i.e. slight volar flexion with radial flexion. Many years ago while working with Dr. Cotton and Dr. Berlin this phase was studied at length and the conclusion arrived at that the cock up was preferable this being particularly desirable in the event of stiffness of the wrist, the position of choice for an ankylosed wrist being in extension. Dr. David Berlin working on the cadaver has shown that the cock-up position gives better apposition. In putting these cases at rest the plaster-of-paris cast is used instead of the ordinary cock-up splint. This fixes the wrist does not require adjustment when properly applied and insures the patient of a continuance of the treatment. Many times with the cock-up splint these patients give up the treatment at the end of 2 to 3 weeks and are never seen again.

Immobilization regardless of how obtained should be maintained for at least 6 weeks, followed by baking and massage for a few weeks. Too much emphasis cannot be placed on the need of 6 weeks immobilization, less time in my opinion being entirely inadequate. This is necessary to allow restoration of the blood supply and the healing of torn ligaments. The cast is applied in the cock-up position with slight radial flexion to include the palm of the hand and the base of the thumb but does not limit the motion of the fingers. Following the removal of the cast a straight splint can be applied for a few days or a flannel bandage applied and motion started at once. Most of these cases seen within the 48 hours following trauma will do well under this routine. The mistake most people make is to shorten the period of absolute rest.

Cases with marked separation or comminution of fragments should be operated on at once removing part or all of the bone.

The third group of cases now comes up for consideration and they represent the crippling ones that have had months of trial with the resultant pain and weakness so often seen. This group represents the cases treated or otherwise, and they are usually untreated or poorly treated, that have gone on to mal-union cavity formation, bone formation along the radial styloid, to a definitely poor result. Men engaged in the heavy occupations requiring the use of the wrist continually are practically totally disabled. Some time ago many of the industrial surgeons were consulted for their opinions regarding the end results of removing part or all of the scaphoid. While some favored total removal and others partial, all agreed that the results were not too good and advised leaving the wrist alone if possible.

Dr. John Adams of Boston, so far as I know was the first one to resort to the graft operation for these cases. It was thought at first that this produced bony union but time has proved that the union is fibrous in many cases. However clinically this operation gives a good result in the few cases tried and should be used more extensively. The remarkable thing about it is that the patients are satisfied and feel entirely relieved from their previous symptoms. In performing this operation, I have grafted a piece of the tibia others make use of the radius on the same arm. Some men believe in the bone peg instead of the graft. The peg operation is much easier but I think that it does not stabilize the parts so well as the graft. Following the operation, the wrist is put up in plaster as above, i.e. dorsal flexion with slight radial flexion. This is kept on for 6 weeks, to be

followed by a straight splint for 10 days, meanwhile instituting baking and massage

CASE 2. N. Y. student, aged 17 years, injured his wrist in December 1930, and injured it again recently. December 1931 graft operation was done, plaster cast was worn 6 weeks, anterior splint 10 days. This boy also had an ununited fracture of the styloid of the ulnar. Figure 3 shows wrist before and immediately after operation. Figure 4 shows wrist 2 months later. Figure 5 shows wrist 9 months later. From an X ray point of view this case appeared to show bony union. Clinically the boy is extremely happy over the result.

At first the X ray films of these cases show what appears to be bony union but as a rule this bony union changes to one of fibrous union at the end of some months judging from experience with a few cases. Case 2, however at the end of 9

months shows what appears to be straight bony union.

SUMMARY

Results in the cases reported to date are much more satisfactory than those operated on by any other method. They require more time for convalescence but the anatomy is undisturbed and the patients themselves feel very much satisfied. They are entirely relieved of their symptoms. Believing that the usual procedure of removing part or all of the scaphoid has not given sufficiently satisfactory results to warrant its routine continuance another operation is brought to the attention of those working in this field. I believe that this graft operation is easily performed, does not change the anatomy of the wrist, and does give excellent results.

FRACTURES OF THE JAWS¹

ROBERT H. IVY, M.D., D.D.S., F.A.C.S., PHILADELPHIA, PENNSYLVANIA

IT is indeed gratifying to have the subject of fractures of the jaw bones included in this symposium on fractures in general because there has been a tendency on the part of the surgeon to underrate their importance or to set them apart as lying exclusively in the field of the specialist.

The surgeon is being confronted with cases of serious injury of the facial bones more and more frequently owing to automobile accidents, and the proper management of such cases demands his earnest consideration. He is often unfamiliar with comparatively simple methods of fixation for fractures of the facial bones, consequently he is likely to pay more attention to repair of the overlying soft tissues leaving the fractures without early reduction and thus allowing secondary deformity to result. These facial injuries are frequently associated with shock, concussion, fracture of the skull, or intracranial hemorrhage, and it is quite natural that emphasis on the more urgent complication should at times cause the facial injury to be more or less disregarded. Consideration for the life of the patient should of course be uppermost, but this should not prevent some attention to the facial injury at an early date in most cases. Early reduction and fixation are of the utmost importance here just as in fractures of other bones, since delayed reduction may result in malunion causing interference with function

and visible disfigurement. Delayed reduction also increases the tendency to infection because these fractures of the jaw bones are generally compound into the mouth. In fracture accompanied by extensive wound of the overlying soft tissues reduction of the fracture should be brought about first and the soft tissue wound closed afterward. Where the reverse procedure has been followed later reduction of the collapsed bone fragments may be difficult or impossible.

In reduction and fixation of fractures of the jaw bones the principle to be borne in mind is restoration of the original occlusion of the upper and lower teeth. Many surgeons following accepted textbook teachings and unfamiliar with really efficient and simple methods which utilize the teeth as points of fixation attempt to bring about the desired result by application of a Barton or other bandage. No amount of pressure with a bandage on the chin will fix a fracture of the mandible when there is any tendency to displacement and if there is no displacement no fixation at all is necessary. It would be just as logical to attempt fixation of a fracture of both bones of the forearm with a bandage alone. Sometimes the surgeon is tempted to try direct wiring or plating of bone fragments. This should never be attempted in recent fractures which communicate with the mouth since it only serves to add to the infection and never gives sufficient fixation

¹Presented in the symposium on the Treatment of Fractures, before the Clinical Congress of the American College of Surgeons, Boston, October 16, 1931.

Cases with marked separation or comminution of fragments should be operated on at once removing part or all of the bone.

The third group of cases now comes up for consideration and they represent the crippling ones that have had months of trial with the resultant pain and weakness so often seen. This group represents the cases treated or otherwise and they are usually untreated or poorly treated, that have gone on to mal-union, cavity formation, bone formation along the radial styloid, to a definitely poor result. Men engaged in the heavy occupations requiring the use of the wrist continually are practically totally disabled. Some time ago many of the industrial surgeons were consulted for their opinions regarding the end results of removing part or all of the scaphoid. While some favored total removal and others partial, all agreed that the results were not too good and advised leaving the wrist alone if possible.

Dr. John Adams of Boston so far as I know was the first one to resort to the graft operation for these cases. It was thought at first that this produced bony union but time has proved that the union is fibrous in many cases. However clinically this operation gives a good result in the few cases tried and should be used more extensively. The remarkable thing about it is that the patients are satisfied and feel entirely relieved from their previous symptoms. In performing this operation, I have grafted a piece of the tibia others make use of the radius on the same arm. Some men believe in the bone peg instead of the graft. The peg operation is much easier but I think that it does not stabilize the parts so well as the graft. Following the operation the wrist is put up in plaster as above i. e., dorsal flexion with slight radial flexion. This is kept on for 6 weeks, to be

Fig 4. a, left figure, Heavy arch bar secured to teeth with wire ligatures for treatment of fracture of upper jaw b attachment of apparatus on upper teeth to plaster head cap holding upper jaw against base of skull

space for feeding. There are certain complicated types of fracture of the mandible requiring special methods of fixation. For information on these methods special works on the subject should be consulted.

Fractures of the maxilla are much less common than those of the mandible. They are often associated with extensive head injuries, fracture of the skull cerebral concussion, etc. There are no powerful muscles attached to the maxilla, consequently displacement of fragments is usually due to the direction of the traumatizing force though sometimes to gravity. Fractures of the maxilla may be unilateral or bilateral.

Unilateral fracture is usually caused by direct force coming from in front or from one side. There is a split in or near the median line of the hard palate and on the labial aspect the fracture line extends horizontally or obliquely backward above the level of the teeth. There are symptoms of contusion of the face and the entire maxillary dental arch on the side of injury is usually depressed. By gentle manipulation, mobility of the fragment can be demonstrated. Many cases can be successfully treated by pushing the fragment back in place until the teeth are in occlusion and then wiring the teeth of the sound side of the maxilla to those of the mandible.

Bilateral fracture of the maxilla is usually caused by direct force from in front or slightly to one side. This type is illustrated by cases in which the passenger's face strikes the steering wheel of a suddenly arrested automobile. In the majority of cases the entire upper jaw is displaced backward and sags downward posteriorly so that the upper teeth are posterior to the lower and only the last molars occlude, leaving a space between the incisors in front (Fig 3). The entire dental arch can be moved as a unit.

Fixation by means of the mandibular teeth is not advisable at first because of the mobility of the lower jaw. Support here should be obtained from the cranium by means of a head apparatus and reversed Kingsley splint. We have had made an emergency apparatus of this type which can be kept on hand in two or three sizes so as to be immediately applicable. It consists of a heavy metal arch bar to be secured to the outer surfaces of the upper teeth with wire ligatures and provided with arms extending out of the mouth on each side for attachment to a plaster-of-paris head cap with straps or heavy elastics (Fig 4). By this means the upper jaw can be gradually guided into position and after a week or 10 days when the upper and lower teeth have regained their occlusion they can be fastened together with wire ligatures for a period of 3 or 4 weeks until union is complete. Reduction of this fracture should be begun as early as possible, because if delayed too long union sets in and it may become very difficult to move the displaced bone by gradual traction. Correction of firm malunion in the upper jaw by operative procedures is generally not to be considered.

A brief consideration of fractures of the malar and nasal bones is not out of place here.

Fracture of the malar or zygomatic bone is always due to direct violence, and usually the breaks occur at or near its junction with other bones, the body of the malar being depressed and often impacted.

A depression is seen in the cheek on the side of the injury, just below the outer corner of the eye while lower down the cheek appears to be swollen. The entire side of the face may be so swollen and oedematous as to mask the deformity. Diplopia may be present, due to the depression of the floor of the orbit or interference with the action of

ocular muscles. Subconjunctival ecchymosis is seen. Epistaxis usually occurs, due to rupture of the maxillary sinus mucosa. The patient complains of numbness of the side of the nose and lip owing to infraorbital nerve injury, and often has difficulty in occluding the teeth owing to interference with the coronoid process of the mandible. Palpation reveals tenderness and irregularity of outline at 4 points: over the zygomatic arch, the junction of the malar with the frontal bone, the lower rim of the orbit, and where the malar joins the maxilla below. A ray examination made with the skull in the vertical position will outline clearly the depressed malar as compared to the normal side.

The depressed bone should be elevated as early as possible, as neglect of this will result in a permanent deformity. Union in malposition occurs rapidly, so reduction should not be delayed beyond a week. Many methods of elevation have been advocated. The most efficient in our hands is that suggested by Gillies which consists in lifting up the bone by a long flat elevator inserted through a small skin incision in the temporal region. The elevator passes through a slit in the temporal fascia and slides down on the temporal muscle beneath the malar. The necessary amount of elevation can be controlled by the fingers placed on the cheek. No fixation is necessary. The incision is closed with a suture, and leaves no visible scar since it is above the hair line.

Fracture of the nasal bones is also due to direct violence. The nasal bones may be thrust directly backward with or without comminution, the septum being crushed or buckled beneath them or the bones may be displaced to one side.

It is desirable to replace the bones if possible before swelling masks the deformity that is, within the first few hours after injury. If postponed for a week or longer union may require dislodgment with a chisel. Fractures with little or no displacement do not require treatment. In recent cases, it generally has been possible to elevate the depressed bones by pushing them up with a closed pair of curved Kelly forceps inserted in the nostril and molding with the fingers externally. The use of intranasal splints is not as a rule satisfactory, but the nose may be packed with gauze soaked in liquid petrolatum for 24 or 48 hours to maintain elevation and control hemorrhage.

Where the nasal bones tend to sag down a mattress suture of fine wire or silkworm gut passed beneath them through the skin from side to side and tied over lead plates resting on the skin will often aid in preserving the prominence of the bridge. Recent cases with lateral deviation also can be corrected by manipulation and recurrence of the deformity may be prevented by Blair's scheme of engaging the lower end of the nasal bone on the deviated side in a loop of fine wire passed through the skin, allowing the ends to pass down across the septum into the vestibule of the mouth on the opposite side and securing them to a molar or premolar tooth.

The main objects of this paper have been to urge upon the surgeon the desirability of early replacement of fragments in fractures of the facial bones, and to call his attention to the availability of simple methods of fixation quickly applicable without special dental laboratory technique.

ACUTE FRACTURES¹

MELVIN S. HENDERSON M.D., F.A.C.S. ROCHESTER, MINNESOTA
Section on Orthopedic Surgery May Clinic

ACUTE fractures are true emergencies. Reduction is generally relatively easy within the first few hours after the accident before muscle spasm has become more or less fixed. Roentgenographic examination of any fracture is essential and only in unavoidable circumstances should it be omitted. Compound fractures should be treated as nearly as possible as one would treat a closed fracture reduction being accomplished at once if practicable. In this paper I shall not consider compound or open fractures as a separate entity but my remarks will be applicable in the main to both types. The open method of treatment should rarely be used for the correction of compound fractures.

DIAGNOSIS

Although the roentgenogram is pre-eminent as an aid in the diagnosis of fractures, it should not be relied upon to the exclusion of physical examination.

The wounded extremity should be carefully examined for abrasions of the skin and contusions, and for injuries to nerves, tendons, muscles and vessels. It is surprising how often musculospiral paralysis is missed at the first examination in fractures of the humerus, all attention being focused on the fracture. Manual examination and manipulation to establish a correct diagnosis is correct in theory but in actual practice it is seldom necessary for the roentgenogram gives much more definite information and makes painful manipulation unnecessary. Comparative measurements as to length particularly in the lower extremity should not be neglected.

With the aid of the roentgenogram it is possible to determine definitely the site of fracture—whether such fracture is in the shaft or in the region of the epiphysis or joint likewise can be determined whether the fracture is comminuted transverse spiral or oblique and whether the fragments are apposed, angulated or never lapped.

In the pioneer days in this country education was restricted largely to the rudiments euphoni-ously referred to as the three R's—Reading, Riting and Rithmetic. We may without any such poetic license restrict the rudiments of the treatment of fractures in three R's also namely Reduction Retention and Restoration.

REDUCTION

Writings on the treatment of fractures coming to us through many centuries have insisted almost universally on the necessity for early reduction. Early reduction however must not be practiced at the expense of thoroughness in diagnosis. Any hospital or individual accepting the care of fractures should see to it that the service provides both promptness and thoroughness, responsibility not being delegated to the inexperienced. The actual care of such fractures should be carried out or closely supervised only by those with sufficient training experience and by no means least interest.

The methods of securing reduction of fractures are legion, although fundamentally there are but three namely manipulation traction and open operation. The result of any attempt at reduction should be definitely recorded with the roentgenogram, preferably also after the retentive apparatus is on.

There should be no quarrel between the closed and open method. It is much better if the open method is to be used to employ it in selected cases at once and not reserve it for use only after the closed method has failed.

Reduction of the fragments to perfect anatomical alignment as a guarantee of restored function is desirable but not always necessary for good function. In fact, insisting on such perfection may in some instances actually do more harm than good. In children it is surprising to see how an early result following reduction and retention of a troublesome fracture of the lower end of the humerus that is anatomically and functionally unsatisfactory in a year or two smooths out anatomically and gives perfect function. Fractures of the ankle without articular injury and in which there is a correct weight bearing line will return to satisfactory function even if the alignment of malleolar fractures is not perfect.

Intra articular fractures, especially if the functioning portion of the joint surface is involved may give particularly poor results and open operation helps but little because the displacement of the fragments is relatively slight and the condition can be improved but little even though the joint is opened. With such fractures much depends on the amount of crushing and actual destruction sustained by the underlying support

Fig. 1. Comminuted trochanteric fracture before reduction.

Fig. 2. Trochanteric fracture reduced and retained by aid of two Kirschner wires.

ing spongy bone. Hemorrhage into the capsule with subsequent fibrosis often leads to a tedious convalescence, and in such cases the aim should be for early joint motion.

Whether or not the open method is to be used for any fracture will depend to a great extent on the individual surgeon—on his inclination, training, and on the equipment at his command. While satisfactory reduction of a given fracture may be obtained by the closed method, satisfactory external fixation and maintenance of alignment may be difficult to accomplish. If so, the surgeon should not hesitate to use some form of internal fixation and thus avoid the dangers of precarious retention. The fact that external fixation must be used in addition to the internal fixation is no sound argument against the use of internal splinting. While I by no means advise open reduction of fractures as a routine method, I value it highly and have used it often with benefit to my patients and with satisfaction and comfort to myself.

Those fractures which in my opinion are best treated by the open method are fractures of the patella, of the olecranon process, of both bones of the forearm, of both bones of the leg, and of the upper third of the femur. I am inclined to include also trochanteric fractures, fractures of the lower third of the femur with great displacement, certain fractures of the surgical neck of the humerus with marked rotation of the head, and comminut-

ed fractures of the head of the radius. Fractures of the clavicle, wrist, and ankle are best treated by the closed method, as are also most of those of the lower end of the humerus. In many instances a fracture seen late, which might have been satisfactorily treated by the closed method soon after the accident, is better treated by the open method.

There is no valid reason why the open method should not be employed for fractures whenever necessary. So far as I know there has never been a fair presentation in the literature on the subject which would tend to prove that the open method gives poorer results in comparable cases than the closed method. The best report, that by the British Medical Association Committee, as a matter of fact tended to indicate that the open method, all things considered, gave even better results than the closed.

RETENTION

Retention of the reduced and approximated fragments, often the greatest problem in the treatment of fractures, may be accomplished by internal means alone or in conjunction with some external means also. After reduction or locking of the fragments together and placing the limb in a neutral position with muscle pull balanced, retention is simpler because the normal muscle pull holds the ends of the bone locked. In a frac-

ture of the humerus, for example, particularly of the upper third, muscle balance with the arm abducted (not beyond 45 degrees) tends to hold the fragments together after reduction, as does also the abducted position with internal rotation in a fracture of the neck of the femur. Plaster of paris with suitable padding affords the best material for external fixation, although splints, if used intelligently and skillfully, may be employed. Generally speaking splints should be retentive and not corrective. Ischemic paralysis due to venous stasis, especially in fractures of the upper extremity, is a dread complication, and it is by no means always due to tight dressings, for I have seen it develop when splints, bandages, or plaster had not been applied. Hemorrhage within muscular fascial planes may produce enough tension to cause ischemia. Prompt recognition of such a happening immediately followed by multiple small incisions to evacuate blood and relieve pressure will prevent the development of ischemia.

Traction, either skeletal or skin, is a great aid in retaining the fragments in alignment, as is best exemplified by the Thomas extension splint. The Thomas splint is a wonderful splint, but we often expect too much of it, for it is by no means automatic.

Open reduction and the use of some form of internal fixation of the fragments in my opinion has been found fault with too much. Metal plates and bands so often disparaged afford an excellent means of controlling difficult fractures and I never hesitate to use them when I feel the situation calls for internal fixation in closed fractures. It is a fine point of surgical judgment to determine when the open method is to be used in compound fractures, since at times it is necessary. Oblique and spiral fractures can often be held nicely by aid of several beef bone screws staggered through at different angles. If something stronger is needed, one or two Parham bands thrown about the fragments are reliable and easily removed when union is complete. I have practically given up use of the beef bone plates since to be of sufficient strength they must be large and heavy and they consequently are slowly absorbed and may remain as permanent foreign bodies. I prefer to use metal plates removing them when they have served their purpose. Autogenous bone grafts may be used for recent fractures but they demand an exacting technique which it is the privilege of but few to possess.

RESTORATION

The length of time that retention is necessary varies in different individuals and to a certain

Fig 3 "Trimalleolar" fracture of ankle.

extent in fractures. The roentgenogram affords the best means of determining the amount of callus and its maturity. Discontinuance of the retentive apparatus is permissible only when callus has developed and aged sufficiently to insure development of bony union. Some such protective apparatus as a walking caliper should be used for fractures of the lower extremity in order to aid in bearing the weight, nor should this precaution be omitted without the consent of the surgeon in charge.

Truly a worrisome point is to decide the time when the fractured extremity may be used. If use is permitted too early, deformity at the site of fracture may ensue, which, if not promptly corrected, leads to permanent malunion. Excessive local tenderness over the site of fracture means an immature callus, and is a danger signal. Light massage and gentle active movements should be conducted without pain. If the fracture is kept in fixation too long, the muscles tend to lose their tone and elasticity and they undergo fibrosis, the fibrous capsule of the contiguous joints contracts, movements become painful, and convalescence is unnecessarily prolonged. With heavy people Pott's fractures of the ankle should be protected in weight bearing by slight elevation

Fig. 4. Relation of concavity to convexity in antero-posterior and lateral views

of the inner side of the sole and heel by an inside T strap and by an outside iron to prevent valgus. Weight bearing should not be permitted in cases of fracture of the neck of the femur until bony trabeculations crossing the line of fracture can clearly be seen in the roentgenogram; this is evidence of union. A fracture of the shaft of the femur, even though it seems clinically to be solid, should always be protected by the use of a walking caliper until bony union is certain.

Massage and heat in some form are of undoubted aid. Active movements are better than passive movements because they promote increased circulation through natural stimulation. Passive manipulations are actually dangerous when left to the inexperienced.

TRIMALLEOLAR FRACTURE OF THE ANKLE AND RECENT FRACTURES OF THE NECK OF THE FEMUR AND TROCHANTER

The two fractures of the lower extremity that leave in their wake the most serious disabilities are certain fractures of the ankle and of the hip. I will again call your attention to one type of fracture of the ankle, which was so forcibly brought to our attention a few years ago by Dr. Cotton of Boston that it is known in many places as Cotton's fracture. It is a Pott's fracture with fracture of the posterior margin of the tibial joint surface causing posterior displacement of the foot. I choose to call it "trimalleolar" fracture of the ankle.

With such a fracture there is a tearing of the internal lateral ligament or fracture of the internal malleolus, fracture of the external malleolus or fibula in the lower $3\frac{1}{2}$ inches (6.5 cm.) and fracture of the posterior tibial margin or posterior malleolus; hence the term, "trimalleolar" (Fig. 3). The too common mistake is to correct only

the lateral displacement, leaving the astragalus displaced posteriorly. If the latter condition remains uncorrected it leads to permanent disability of no inconsiderable degree, and it is the one fracture of the ankle that should always be kept in mind. It rarely requires open operation and should be reduced as one would reduce an ordinary fracture of both malleoli, but care should be taken that the foot is brought forward and that the astragalus is replaced in normal position in the mortise between the malleoli. A good anteroposterior film of the ankle joint shows that there is normally a slight concavity in the upper surface of the astragalus, and into this should fit the slight convexity on the articulating surface of the lower end of the tibia. Laterally the opposite is true: there is a convexity on the upper surface of the astragalus which fits into a concavity in the lower articulating surface of the tibia (Fig. 4). If these two surfaces are seen to fit when viewed anteroposteriorly and laterally little attention need be paid to slight displacement of the malleoli.

The surgical bugaboo in fractures of the neck of the femur is non-union. The old teaching that non-union should be expected in fractures of the hip has long since been discarded, largely through the teaching of Whitman and the adoption of his abduction treatment. Taken by and large, the Whitman method has given the best results thus far obtained. It remained however for a Boston surgeon to offer a method which necessitates an operative procedure but not necessarily a formidable one, and in my opinion promises a higher percentage of cures. Smith-Petersen, by the use of his flange-nail, has afforded us, I believe, a most valuable method of treating these fractures and one that bids fair to give better results than any other method. I have offered a modification or an aid to his method which I found had also been advocated by Johansson of Gothenburg, Sweden, and King of Australia.

The difficulty in the use of the Smith-Petersen nail is in placing it accurately. The modification mentioned, which is shown in Figure 5, briefly is as follows. The hip should be reduced in the ordinary manner as advocated by Whitman, and anteroposterior and lateral roentgenograms taken to be certain that the position is correct. A Kirschner wire is then introduced through the trochanter neck, and head and a slight distance into the acetabular wall. Anteroposterior and lateral roentgenograms are taken to determine that the position of the wire is correct. If the position is not correct the wire can easily be withdrawn and re-inserted. When satisfied that the line of the wire is correct, a special cannulated

Fig. 5. a, Kirschner wire *in situ* through trochanter, neck, and head and into acetabular wall. Insert fracture before reduction. b, Smith-Petersen nail threaded over wire. c, Wire removed leaving Smith-Petersen nail in position.

Smith-Petersen nail is threaded over the wire and driven in. Another anteroposterior film is taken (or the fluoroscope may be used) and discloses whether the nail is safely embedded although it should not be so far in as to engage the acetabulum. This is the only untoward thing that may happen, because the nail must follow the wire. When it is determined that the nail does not engage the acetabulum the wire is withdrawn (Fig. 5) the wound closed and a plaster-of-Paris cast applied from the middle of the leg up to and including the thorax. The cast is split at the end of a week and movement of the hip begun. At the end of 3 weeks the cast can be removed and the patient allowed to be up on crutches. When roentgenological examination discloses bony union the nail may be withdrawn usually about 5 months after the operation.

Fractures of the trochanter in my experience unite readily although malposition with shortening is far too common and, contrary to the usual teaching, not easy to prevent. The most satisfactory method we have used is after reducing the fracture on the fracture table, to place two Kirschner wires at different angles through the trochanter and well into the neck (Fig. 1). This will steady the fragments and prevent their slipping while in the cast or extension splint. These fractures are often comminuted and far more extensive than appears in the roentgenogram, (Fig. 2), making it difficult to lock the fragments together firmly enough to prevent the strong pelvic thigh muscles from causing angulation. The wires used as pins prevent this and they are readily removed under local anesthesia when the fracture is united.

BONE GRAFT FOR NON-UNION OF THE CARPAL SCAPHOID¹

GORDON MURRAY M.D. F.R.C.S. (ENG.) TORONTO, CANADA

WHEN a patient complains of a 'sprained wrist' with symptoms lasting more than 2 weeks, the possibility of a fracture of the carpal scaphoid should be considered and the necessary investigation undertaken. If examination shows a fair range of movement of the wrist joint in all directions, but limitation at the extremes of all movements, with tenderness in the anatomical snuffbox when the hand is adducted, and over the dorsal and palmar surfaces of the scaphoid with negative findings elsewhere, it is probable that there is a fracture of the scaphoid. If these findings persist for months or years after an injury causing symptoms in the wrist joint, the possibility of non-union of a fractured scaphoid should be considered.

X-rays taken of the carpal scaphoid in the anteroposterior and oblique directions usually provide the necessary evidence, but recent fractures may be difficult to see with X-rays taken in various directions. There are cases of recent fracture, easily diagnosed clinically in which the first roentgenograms do not show the lesion although plates taken a few weeks later will show obvious signs of fracture. Older fractures with non-union are seen more easily owing to the early rarefying osteitis and fibrous union, and later sclerosis of the adjacent margins of the fragments.

Fractures of the tuberosity always unite if the fragments are in apposition, and those through the intra-articular surfaces about the waist of the bone, which are the most common, may unite if treated. Johnson has shown experimentally that there is an adequate blood supply to the bone as a whole, and to both fragments, in case of fracture. He showed also that the type of reaction in fracture of the scaphoid is similar to that in other bones, but is more localized to the fracture line as there is so little periosteum to assist in the formation of subperiosteal callus. The formation of bone in the callus is slower than in other fractures.

Adams and Leonard say that untreated fractures of the scaphoid always result in non-union, and with the usual form of treatment a small percentage shows union. Grace supports this view with a report of cases showing a high percentage of non-union in those treated by immobilization for a period varying from 6 to 8 weeks. Boehler, on the other hand, states that most fractures of this bone unite if treated early by prolonged

fixation, and this agrees with our results. However, there are many injured wrists treated as sprains without fixation which provide the cases of fracture with non-union.

Certain anomalies should be kept in mind to prevent confusion in making a diagnosis of fracture and non-union. Ordinarily the center of ossification appears in the sixth year but there may be 2 centers and these may not unite but persist to form 2 bones. Rarely the os centrale may persist as a third bone.

Methods of treatment that have been advocated for non-union are excision of one or both fragments or of all the bones in the proximal row including the fragments of the scaphoid. Any one of those operations leaves a deformed wrist with some permanent disability in the form of impaired function and frequently with pain on active use of the hand (Grace).

If the individual with non-union of a fractured scaphoid is able to follow a sedentary occupation and avoid energetic use of the hand he may have little discomfort but if his life includes heavy labor sport, or other strenuous vocation where full range of movement of the wrist is important, the best prospects are offered by a bone graft. There is a report of one case in which this operation was used, but the method has not come into general use. In our cases with non-union this form of treatment has yielded the best results. It is essential to have X-ray evidence that both fragments are viable and in apposition, and that there is no arthritis.

OPERATIVE TECHNIQUE

With the hand in full adduction a curved incision is made along the radial surface of the wrist joint extending about $1\frac{1}{4}$ inches upward and downward from the radial facet of the scaphoid. The ends of the incision are curved toward the posterior surface of the wrist, and the convexity anteriorly should reach the tendon of the abductor pollicis longus. The radial nerve and vessels and the abductor tendons of the thumb are retracted anteriorly the extensor pollicis longus tendon posteriorly. This provides exposure of the tuberosity of the scaphoid. A small transverse opening is made through the dorsal capsule of the wrist joint, exposing the dorsal surface of the radial facet of the scaphoid, and on this surface the fracture line is apparent. If the other bones

of the carpus have not been disturbed by the injury the fragments of the scaphoid will not be displaced, and in that case the fracture line is not disturbed by curetting, etc. After clearing the most prominent area of the tuberosity a small nick is made in the bone at this point with rongeurs, in order to provide for countersinking of the graft and prevention of bone proliferation which might interfere with abduction of the wrist joint.

With about a $\frac{3}{16}$ bit, a hole is drilled, beginning at a nick in the tuberosity through the proximal fragment, across the fracture line and into the distal fragment. Great care is necessary to line the drill properly, assisted by observations through the dorsal window so that no cartilaginous surface is damaged. The depth of the drill hole after

the fracture line is crossed should be measured every few millimeters to prevent damage to the semilunar facet of the scaphoid by going too far.

A suitable piece of cortical bone is removed from the tibia and shaped to fit snugly. It is passed well through into the medial fragment, care being taken that the fragments are not separated, and it is then cut so as to leave no projection. The dorsal ligament is repaired.

The hand is supported in a circular plaster in a cock up position for 8 weeks. All our cases in the General Hospital had X. ray evidence of bony union after this period, and within a few months the fracture line had disappeared. There was complete restoration of function, with a full range of movement in all directions without pain and with normal grip.

COLLES' FRACTURE¹

HARRY PLATT M.D., M.S. F.R.C.S. MANCHESTER, ENGLAND

THE subject of Colles fracture, though admittedly well worn, presents many features of interest and importance to the surgeon whose field of practice embraces the treatment of bone and joint injuries. In hospitals where the segregation of fractures is an essential part of the surgical organization it should be possible to guarantee to all patients with a Colles fracture a wellnigh perfect anatomical and functional result. But a considerable proportion—possibly the majority of Colles fractures—must inevitably be treated under less ideal conditions. In Great Britain at least, (I am unable to speak for the United States of America) this common fracture of the wrist is still traditionally regarded as an injury which may be safely left to the sole jurisdiction of the family practitioner. Statistics obtained from large insurance companies relating to periods of disability, following injuries of this type indicate quite clearly that the treatment of Colles fracture, except in the hands of the expert, leaves much to be desired. On the other hand, we must appreciate the fact that even under the conditions of an organized fracture service, the mechanical difficulties encountered in the treatment of Colles fracture in all its phases cannot be lightly dismissed. I believe that the quality of the work of any hospital fracture clinic may be judged best by the precision shown in dealing with these fractures.

The successful treatment of this injury calls for three essentials (1) a high degree of manipulative dexterity (2) accurate and uninterrupted control of the fracture throughout the stage of consolidation and (3) a knowledge of the fundamental principles concerned in the mobilization of an injured joint. Failure in any one particular will mean an indifferent or even a disastrous result.

ANATOMICAL AND CLINICAL CONSIDERATIONS

It is unnecessary to enter into a detailed discussion of the anatomical and clinical picture of a fracture which is familiar to every practicing surgeon. Certain facts, however are worthy of emphasis.

1 In the first place *gross displacement* reproducing the characteristic dinner fork deformity of the older textbooks is relatively uncommon. But varying degrees of displacement obvious on inspection in most cases to the practiced eye, or clearly revealed in radiograms, occur in at least 75

per cent of the Colles fractures seen in ordinary hospital casualty practice. It must be remembered that minor degrees of displacement become masked after some hours by the swelling due to the accumulation of the hematoma around the fracture line.

2 In my own experience the classical *triple displacement* of the lower fragment is present in a minority of cases. Either backward displacement *en masse* or radial deviation may be absent. In many Colles fractures the deformity simply consists of a backward tilt of the lower end of the radius, which, when well marked, reverses the plane of the lower articular surface. In the absence of crepitus this deformity is frequently overlooked, in spite of the loss of the normal concavity of the lower end of the radius, which is so striking a clinical sign.

3 *Commminution* is a factor to be reckoned with in many fractures, and the direct involvement of the wrist joint by a secondary line of fracture combined with spreading of the multiple fragments, adds to the difficulty of the problem of ultimate mobilization.

4 Disturbance of the *inferior radio-ulnar* articulation must also be considered. In not less than 50 per cent of Colles fractures the fracture line on its mesial aspect reaches the upper limit of the articular facet for the head of the ulna, or enters the joint lower down. I have not been able to satisfy myself that involvement of the radio-ulnar joint in this fashion materially affects the function of rotation of the forearm, provided the injured joint is mobilized with discretion. Much more serious, however is the disturbance which may result from a fracture of the ulnar styloid process at its base, or the equivalent injury—detachment of the fibrocartilage from the lower end of the ulna. As regards the frequency of this latter complication I have no statistical data, for clinical proof of its existence is rarely forthcoming. This point in the anatomy of Colles fracture has exercised the minds of surgeons for many generations.

TREATMENT

Technique of reduction. In a recent fracture comparatively little force is required to effect a complete and accurate correction of the displacement of the lower fragment in all three planes. Reduction by manual pressure applied directly to the bony fragments, as taught by the late Sir

¹Presented at the symposium on the Treatment of Fractures, before the Clinical Congress of the American College of Surgeons, Boston, October 14, 1934.

Robert Jones, is, in my judgment, by far the most effective maneuver at our disposal. As an auxiliary force, traction applied via the hand has a distinct place—(a) in the early stage of reduction, to disengage the lower fragment, and (b) in the last stage, when the hand is brought into the position of palmar flexion and adduction. It should hardly be necessary to stress the importance of confirming the accuracy of reduction by radiograms. No radiogram should be passed unless the restoration of the normal plane of the lower articular surface of the radius can be convincingly demonstrated.

In neglected fractures manipulative reduction is a far more formidable undertaking but in my own clinic we are accustomed to correct a backward rotation deformity by manual force alone up to the end of the third week and sometimes even later. If this effort fails unless there is gross deformity, I believe the fracture should be left uncorrected. My experience in the results of open correction in Colles' fracture has been most disappointing. It must be obvious that after an osteotomy has traversed the region of the fracture accurate dovetailing of the serrated edges of the fragments cannot be achieved.

Technique of fixation. It is often taught that the method of fixation of any fracture is of secondary importance compared with the accuracy of reduction. In my judgment this is a dangerous doctrine when applied indiscriminately to Colles' fracture. In reading the writings of the older surgeons on this subject—which on the anatomy of the fracture are so illuminating—one is struck by the fact that many of the special splints introduced for the control of the fracture have been designed on unsound principles. After the effective reduction of a Colles' fracture the optimum position of the limb is with the wrist in moderate palmar flexion and the hand slightly adducted. This is a natural position of rest in which the structures on the flexor and extensor aspects of the wrist joint are in a state of reciprocal tension. I have little use for the position of extreme palmar flexion, which to me implies a confession of failure to disengage and correct the backward tilt of the lower fragment completely. Moreover, it is a sound principle that an injured joint should not be fixed for any length of time in a position of abnormal strain. I am also unable to understand the rationale of fixing a Colles' fracture with the wrist in dorsiflexion—a position which undoubtedly favors a recurrence of the backward tilt.

The essential factor in fixation of a Colles' fracture is the control of the posterior aspect of the whole forearm wrist, and dorsum of the hand

as far as the metacarpophalangeal joints. No standard splints, ancient or modern, can compare with a plaster-of Paris strip applied directly to the skin of the extensor surface. The plaster "gutter" should embrace not more than two-thirds of the circumference of the limb should be closely moulded over the lower end of the radius, and trimmed to allow free movements of the thumb. During the application of the plaster, and until its setting is complete, strong traction must be maintained on the hand by an assistant. At the same time the fracture is moulded between the thenar eminences of the surgeon. This enables one to ensure both the final correction of the backward tilt and the approximation of the multiple fragments where comminution is present.

Period of immobilization. Conflicting views are held regarding the length of time a Colles' fracture should be completely immobilized. In this connection I suggest that two guiding principles should determine our practice: (1) No Colles' fracture in which there has been an appreciable displacement is firmly consolidated before the end of the fifth or sixth week. (2) Every injured joint needs an adequate period of complete rest before being subjected to strain. In the treatment of elbow joint fractures in children the necessity for absolute rest is universally admitted, but in relation to the treatment of Colles' fracture there is no such unanimity. I am convinced beyond all doubt that the practice of immobilizing a Colles' fracture without interruption for a minimum period of 5 weeks is based on correct physiological and mechanical principles. During this stage the limb should not, of course, be entirely idle. Following the teaching of Boehler, the patient is instructed to carry out daily a regular scheme of activity in all joints of the upper limb except those which for the time being are securely immobilized, viz., the wrist and inferior radio-ulnar joints. For the greater part of this time no sling should be worn.

Experience in the treatment of Colles' fracture on a large scale has impressed me with the potential risks of recurrence of deformity, in spite of careful fixation. This tendency to secondary deformity is seen after the second week. It has been said with some truth that secondary deformation often represents a failure to obtain a complete reduction of the fracture at the time of the original setting. I am satisfied however, that in certain circumstances after a perfect primary reduction a backward tilt of the lower fragment may reappear at the critical period between the second and third weeks. For this reason it is wise always to check the position of the fracture by

radiograms after the second week. If the slightest change is discovered in the position of the lower fragment the plaster should be removed, the fracture remoulded and a new plaster applied. This is usually possible without anesthesia. Since the adoption of this routine in my own fracture clinic secondary deformity has become practically unknown.

Mobilization. On removal of the plaster gutter where the fracture has been immobilized without interruption for not less than 5 weeks, the excellent nutritional condition of the limb is always striking. There is no edema and all digital joints are supple and painless. The wrist and inferior radio-ulnar joints also allow a short range of movement without discomfort. Although in the majority of cases the patient may now be entrusted to work out his own salvation by active movements, he should not be left entirely to his own devices. The pace of mobilization should be determined by the anatomy of the fracture. Where there has been marked comminution, or involvement of the inferior radio-ulnar articulation, or where the wrist is the seat of a pre-existing arthritis, the joints should be allowed to take strain very gradually. Overzealous active mobilization in such circumstances may spoil the ultimate functional result. Forced mobilization in any fracture will be disastrous.

The services of a masseuse, except in a supervisory capacity, are redundant in a considerable proportion of Colles' fractures. But in many of the older patients, particularly those with ar-

thritic wrists, a judicious scheme of physical treatment is helpful at this stage.

RESULTS

Some years ago, when the subject of Colles' fracture had excited renewed interest among British surgeons, I was able to investigate the late results in 111 of the patients treated during the 1925-28 period in my hospital fracture service. The findings are shown in the table.

Result	Fractures without displacement	Fractures with displacement
Excellent (including perfect)	18	74
Good—that is, able to do original work, but some slight objective or subjective defect	6	10
Poor		3

In a more recent series of 200 consecutive cases treated under similar circumstances, the average period of total disability has been reduced to 8 weeks. These figures are in no way exceptional. I quote them merely to illustrate the quality of result which is now demanded from an organized hospital fracture service where there is unity of control.

It is the duty of those of us who are responsible for teaching the treatment of fractures in the medical schools to ensure that our students, both undergraduate and postgraduate, will be more competent in the future to handle a common injury like Colles' fracture with some degree of precision. We can do this only if our practice is founded on sound physiological and mechanical principles.

RECURRENT DISLOCATION OF THE SHOULDER¹

TOUFICK NICOLA, M.D., F.A.C.S. NEW YORK, NEW YORK

THIS article is written because of the many inquiries regarding the operation for recurrent dislocation of the shoulder which the author first published in 1929.¹

The operation was worked out on the cadaver in 1926 in the dissecting room of the New York Post-Graduate Hospital. On the cadaver the head of the humerus could not be completely dislocated, even though all the muscles and capsule were severed.

The idea of the operation was obtained from an articulated skeleton in which the humerus was held in place by a metal pin, passed through the head of the humerus and attached to the upper angle of the glenoid fossa.
